CLINICAL LECTURES

ON MALIGNANT DISEASES OF THE UTERUS.

BY WM. H. WATHEN, M.D.,

Professor of Obstetrics and Gynæcology in Kentucky School of Medicine, Louisville.

Reported by A. H. KELCH, M.D. (Stenographer).

LECTURE II.

TREATMENT OF UTERINE CANCER.

GENTLEMEN,—Until about thirty years ago no radical treatment was resorted to in these cases but the actual cautery, nor was there any that was supposed to be of any decided benefit except this. Afterwards, when Chassaignac invented the écraseur, these growths were amputated by it. Finally, when Middledorpf, of Breslau, devised the electro-cautery, the cervix was amputated by that means. It was amputated later by the knife or scissors; then, after the operation for amputation, escharotics were applied. The method now most highly recommended is to remove as much of the growth as possible, after the fashion which best suits our convenience, and then apply either the actual or the potential cautery. Until quite recently it has been customary, where the cervix was amputated above the diseased structure, simply to bring the mucous membrane over the stump of the amputated cervix and allow it to unite; but now this treatment has generally been abandoned, and in most instances where a cancerous growth is removed some form of cautery is applied. Dr. Sims takes strong ground in this direction. He claims that formerly, after amputation alone, the disease sooner or later invariably recurred; but that since he has followed the amputation by the application of some kind of cautery such is not the rule. Dr. Reamy, of Cincinnati, practises after this fashion.

Now, it seems to me that this is a little too extreme, and that there is no reason why the cancerous growth should recur any sooner after the entire removal by the knife, écraseur, galvanic cautery, or Wathen's serrated scissors, than it should after removal with the subsequent application of caustic; and I am confident that in those cases where Dr. Sims amputated the cervix and then found a constant recurrence of the trouble, the difficulty lay in the fact that he did not remove all the cancerous growth, and that his better success since is due to the fact that the cancerous growth left after the amputation is destroyed by the slough produced by the caustic. When we amputate the neck above the diseased structure and bring the healthy edges together, there results comparatively no cicatricial tissue,—we leave the cervix in a healthy condition; whereas after the application of caustic there is an immense deal of cicatricial tissue that is less able to resist the invasion or ravages of disease. We know that when disease is developed in the system it is most apt to attack that organ or part which has the least power of resistance, and for this reason we would conclude that malignant disease of the uterus would be more liable to recur after the amputation or removal followed by cauterization than after the operation of amputation alone. There is a difference of opinion as to the kind of caustic to be applied. One author has a preference for one, and another for another. Dr. Sims is partial to chloride of zinc; others have used bromine, and claim that this is better than any other. Some use the concentrated solution of sulphate of zinc; others, fuming nitric acid.

I can see very little advantage in one caustic over another, provided the caustic used will penetrate into the diseased tissue and produce a slough. Some think that bromine has a peculiar tendency to invade diseased structures. In the selection of a caustic, that which is most manageable and causes least pain, other things being equal, should be preferred. Nitric acid is more easily applied, more under our control, less likely to cause injury to surrounding structures, and causes less pain. Whatever kind be used, it must be applied thoroughly, must be brought into contact with every particle of diseased structure, and must be prevented from coming in contact with and injuring healthy tissues. If the amputation is to be performed when the disease has not extended up to the vaginal attachment, I consider no instrument so well adapted to the removal of the cervix as Wathen's serrated scissors. By its use hemorrhage is prevented and

351701

union of the cut edges occurs. After the amputation you may unite the intra- and extra-cervical mucous membrane, just as you would in amputation of the cervix for any other cause. When the disease has extended above the infra-vaginal cervix into the tissue of the supra-vaginal part, or through the internal os, then, of course, no amputating instrument will be available, and the proper procedure is to tear or cut this tissue away with the scoop, forceps, tenaculum, or scissors, or by any means, until all, if possible, is removed. In these instances it is difficult to cut away all the diseased structures, and you must be very careful not to invade adjacent organs or cavities. The disease often extends through the cervix almost out to the peritoneal investment, and unless you practise great care there is danger of cutting through into the peritoneal cavity. It is often better first to take the scissors and afterwards some sort of scoop or curette. On account of the severe hemorrhage that often complicates this operation, some instrument should be devised to accomplish this purpose better than any we have at present. If we had a scoop with evenly and sharply serrated edges, we could remove this tissue just as easily as if the edge was only sharp, and thus be able to prevent the hemorrhage to a considerable extent. So I would recommend a scoop somewhat similar to that devised by Prof. Thomas for the removal of uterine fibroids. With this you should continue carefully to remove the diseased structure until you have taken, if possible, every particle away. You can always detect if any remains, because it feels hard and gristly.

During the operation we must always be prepared for hemorrhage, and it is well to have two or three pairs of catch-forceps by which to pick up the little arteries as they begin to bleed. You ought to have several whalebone bougies or sounds wrapped with cotton and dipped in a saturated solution of alum or diluted Monsel's solution, which may be introduced into the uterine cavity, plugging the cervical canal if necessary. The operation should be performed as rapidly and with as much facility as possible. When it is over, if the hemorrhage is profuse you will have to control it by the application of styptic cotton. If it is not profuse, you may apply your caustic at once; in other words, if you can control the hemorrhage and bring the parts into a dry condition, you may then at once apply the cautery.

Often a little pledget of cotton wet in the persulphate of iron solution, or in a saturated solution of alum, and packed into the canal, will control it. If not, you may apply a number of vaginal pledgets wet in a weak solution of carbolic acid, so that the vagina is thoroughly and perfectly filled by the cotton. If the hemorrhage continues, you must remove the cotton and reapply the styptic and tampon. After twenty-four hours you may remove the lower third of the tampon. After the second day you may remove all, except that part in the cervical canal, which should be left in position until suppuration is set up and it is separated by that means. If you attempt to remove it by force, it being firmly adherent to the surface, there will be danger of furious hemorrhage. After the tampon has all come away, you must apply your caustic. If you select the chloride of zinc, it should be made in a strength of one drachm of the chloride to two of water, or of equal parts; or you may use bromine dissolved in alcohol, from one part to ten to one part to five; or you may use a saturated solution of sulphate of zinc, or pure fuming nitric acid. It is generally not necessary to use the chloride of zinc in greater strength than one part to two, or the bromine stronger than one part to ten of alcohol. When you use the bromine or the chloride of zinc, you should first wet your pledgets of cotton in the solution and squeeze them nearly dry, and then place them up in the cavity in contact with every part of the raw surface, in the form of a tampon. You now apply a cotton tampon wet in a solution of bicarbonate of sodium, so as to neutralize the bromine or chloride of zinc that may come out into the vagina. This has not the power of neutralizing it completely,—there is nothing known that will do so,—but in default of anything more effective we use this. Unless the precaution be taken to do this, the caustic may cause decided injury to the vaginal mucous membrane, and several days afterwards, when you remove the tampon, you will find the vagina hardened and contracted. The pain after the application is oftentimes very intense, requiring large doses of opium or morphia. Ordinarily we now have the pain nearly entirely under control by the hypodermic injection of morphia.

During this treatment the patient should be kept in the horizontal position. After thirty-six or forty-eight hours the tampon may be removed from the vagina; and again be careful not to disturb the little pledgets of cotton in the cervical canal upon which you have placed the caustic. Let them remain until suppuration has occurred, and they will of themselves come away in the course of four or five days. After they have come away you will find the surface of a dry, grayish color, and in the course of a few days you will have a slough coming away about one-sixteenth of an inch in thickness, leaving a healthy granulating surface, which will heal under the use of weak injections of carbolized water. You can bring the nitric acid directly in contact with every particle of the raw surface without injuring any of the healthy structures. You can apply it by wrapping a whalebone bougie or dresser with cotton, dipping it in the acid, and applying it up in the uterus, bringing it into contact with every part of the raw surface. You can have a solution of bicarbonate of sodium ready, so that if any of the acid comes in contact with healthy tissue it is immediately neutralized by the soda. As soon as the caustic applicator is withdrawn, introduce into the cervical canal another that has cotton wrapped around it and wet in a solution of bicarbonate of sodium, so it neutralizes any superabundance of the caustic within the canal. You may also pour the solution into the vagina, and in this way neutralize the acid. I have had no difficulty at all with the nitric acid, and have found it to produce no great amount of pain, and after it is used it leaves the surface in a healthy, granulating condition. Here it is proper to call your attention to the necessity of being very careful in operating upon and tamponing the cervical canal and uterine cavity, especially when the disease has extended out nearly to the peritoneal covering of the uterus. There are instances where the instrument in the operation has cut through the peritoneal coat of the uterus, also where the cavity was tamponed so tightly as to cause rupture directly through the walls; again, where this has not occurred, the circulation has been cut off, causing sloughing of the tissues. Be careful, then, not to press it in so tightly as to cause, either primarily or secondarily, an opening through the uterine tissue into the peritoneal cavity.

ORIGINAL COMMUNICATIONS.

THE TREATMENT OF DYSMENORRHŒA BY ELECTRICITY.

BY WM. R. D. BLACKWOOD, M.D.,

Attending Physician to St. Mary's Hospital.

(*Read before the Philadelphia County Medical Society, Sept. 8, 1880.*)

I HAVE often wondered how the idea became so universally prevalent among intelligent women that pain is an essential phenomenon of menstruation. Dysmenorrhœa is a wide-spread and intractable malady, and its treatment presents many difficulties to all practitioners, and insurmountable ones to those who are unskilled in surgery, for it is merely a symptom of abnormal uterine or ovarian condition, which, as ordinarily treated, requires mechanical correction in the majority of cases.

Four varieties may be conveniently recognized, although each author you consult may differ on this point. The first in frequency in my own cases is the *neuralgic*, which may be either ovarian or uterine in origin, and here pain is not confined to the pelvic organs, but invades other and distant regions, and is sharp and knife-like, with paroxysmal attacks of acute suffering. The higher class of patients, especially those young ladies who are popularly supposed to be "finishing their education," supply the greater number of such cases.

Next we have the *congestive* variety, found in those affected with coexisting uterine disorder of other type, caused by impeded circulation through direct or indirect pressure on the pelvic viscera, owing to errors in dress, habit, or occupation. Here the pain is dull, heavy, and aching, and is ordinarily confined to the pelvis and lumbar region. Married women who have had a bad "getting-up" after confinement, or who have repeatedly miscarried, are apt to be found in this class, which is second in frequency.

The third group includes the cases in which some *mechanical* obstruction exists, such as flexion or cervical stenosis. With this type we have pain preceding the appearance of the flow, and the suffering is intense. Establishment of the discharge usually greatly mitigates or abolishes the agony endured by this class. It may exist in single or married women, and in the latter it is generally accompanied by sterility.

The last and least frequent variety is the *membranous*. In this class the suffering is severe and continuous, ceasing only upon denidation or detachment and expulsion of the membrane through a forcible dilatation of the cervical canal either by surgical assistance or by the unaided effort of nature. The variety is, in my belief, rare, my own experience being limited to a single typical case, although practitioners have told me that they often meet with well-defined examples.

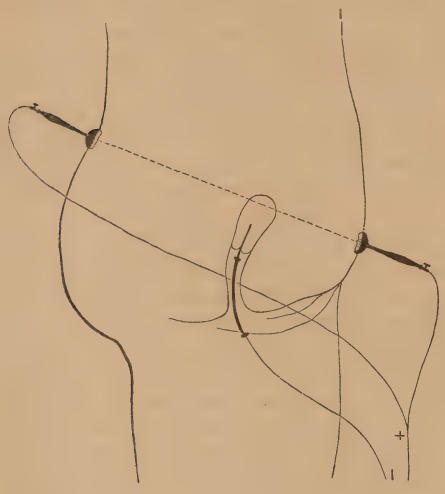
Many methods of treatment have been advocated, some entirely surgical and heroic in plan, others wholly medical, with frequently illogical leanings. All of them are liable to fail at times, and thus the prognosis is rendered doubtful. Any addition to our armamentarium under such circumstances is acceptable; and, if it presents evidence of value, a thorough trial should be accorded it,—not by a few, but by all who profess to treat this immensely difficult and common complaint.

No one agent, nor any series of combined remedies, has been so successful or so satisfactory to me as electricity in the treatment of all varieties of dysmenorrhœa; and yet, in view of the undeniable power to *relieve pain* of whatever kind which this invaluable therapeutic agent is known to possess, its employment has here been singularly neglected even by those who make medical electricity a specialty. In looking over a dozen works on electro-therapeutics I have found in them few subjects which have received less attention, and many comparatively trivial ones which have had much more. My own ideas on the merits of electricity are resultant upon a closely observed list of carefully recorded examples now numerous enough to afford stable ground for the statement made. As many of these cases date back fifteen years, and as the greater number of them have remained under my care during that period, I have had ample opportunity of watching the permanence of the results obtained,—a matter of exceeding importance, for a goodly proportion of them had been more or less benefited by treatment at the hands of physicians before coming into my charge, the improvement in their condition, however, being transitory. Among my earliest patients, and one of the worst to manage, was a lady whose case may be briefly stated.

Miss H. menstruated for the first time during her fourteenth year, being at that time a nervous, undeveloped girl. She had much pain periodically before menstruation was established, and this increased until she was compelled to spend the first three days of each period in bed. When I first saw her she was in her twenty-ninth year, and had endured fifteen years of martyrdom; for, although the dysmenorrhœa troubled her one-fifth of each month, she required almost all the rest to recover any degree of tone and comfort,—a miserable life to lead. She had been under varied professional care, with now and then very slight relief, before seeing me. She had undergone two attacks of pelvic cellulitis, undoubtedly resultant from the use of a stem-pessary, and naturally, therefore, she dreaded any local treatment. I found a sharp retroflexion, tender ovaries, irritable bladder, weary spine, feeble digestion, diffused neuralgia,—in short, a wreck.

With coaxing and careful method I went through the usual plans in vogue and somewhat relieved her general health. Tonics enriched her blood; massage of the abdomen and regular effort relieved her constipation; sun-baths with friction of the entire body brightened her spirits; but no amount of work of any kind relieved her flexion, and her monthly pain was nearly as bad as ever. I tried hard for eleven months to do her justice, and became thoroughly disheartened at my failure. One evening, when I had almost decided to throw up the case, she asked me why I did not try electricity, as I had with a friend of hers. I explained to her the difference between the cases, and doubted the advisability of employing the battery; but, for curiosity, I faradized her uterus and repeated the treatment daily during the week preceding her monthly period. Her menses appeared punctually, as they always did, but, for the first time in her life, *entirely without pain!* She was unwell eight days, an increase of two days in duration, and lost considerably more blood than at any previous time in her recollection. This peculiarity did not again happen; and I may here say that the phenomenon alluded to is not uncommon under electrical treatment, and it is usually confined to the first period. The flow is also frequently hastened, coming on a day or so too soon in some instances, or even a week anticipatory of the expected date. The regular course is, as a rule, thereafter at the habitual interval.

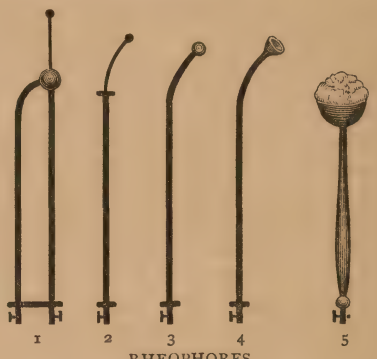
One week subsequent to the cessation of her menstruation I placed her under treatment again, using the induced current twice a week until the week before the next period, when the applications were made every second day. The result was precisely as before,—no suffering whatever. Nothing aside from electricity was administered. I now proposed discontinuing treatment, but she would not hear of it; and consequently the sittings were prolonged for the ensuing three months, when I insisted upon their cessation. She had by this time become a very different person in feeling and appearance. For fourteen months thereafter she had no difficulty whatever; but, owing probably to a wetting in a summer storm, she had a slight recurrence of uterine pain, and at once demanded a renewal of the applications. Keeping her under care a couple of months sufficed, and for many years she has been a thoroughly healthy and grateful lady. The flexion still exists, but is decidedly less rigid; yet all other difficulties are abolished.



The case just related made a deep impression on my mind, and also started a train of others which gave further material for experiment. One of these was that of Miss R., a young lady nineteen years old, and a habitual sufferer. She was stout beyond the average, and had a congested uterus and leucorrhœa, with the usual attending symptoms. I tried leeching, scarification, and glycerin tampons to the cervix, applications of carbolic acid and iodine to the cervical canal and to the fundus in the intervals, together with full dilatation just before the period, associated with appropriate constitutional measures. Three or four months of similar manipulation helped her a little, but not much. Without losing more time, faradization was commenced, and improvement was decidedly established. Three months of bi-weekly applications cured her without any accessory therapeutic measures. She is a type of a numerous list in which similar results were attained.

Miss A. is a good example of the first class,—the nervous or neuralgic. She endured very severe local pain throughout her period, with associate facial and mammary neuralgia. Her womb was free from flexion, displacement, or congestion; the flow was promptly established at the proper time, and was normal in amount and duration; yet she was fast becoming a confirmed invalid. The list of antineuralgics was fully tested; phosphorus, cod-liver oil, malt, and such like brain-foods were pushed; but the sole relief was morphia hypodermically and in full doses. Induced currents were begun, and relief at once was had. Nevertheless, the desired result was not fully secured. Galvanism was therefore substituted, and soon thereafter the victory was complete. In all purely neuralgic cases, as in this, I have found galvanism notably superior to faradic electricity, especially in clinching the business after an impression has been made.

Mrs. F., an old personal friend, consulted me after considerable reluctance from excessive modesty, and she afforded me, as previously stated, the only opportunity I have had in twenty years of seeing a case of pure so-called membranous dysmenorrhœa. She suffered extremely from the commencement during four days, when the entire womb-lining would be discharged. She had dysmenorrhœa and endured decided cerebral congestion during the period. I had by this time a high opinion of the utility of electrical measures, and she went into training at once. Galvanism was tried first, but had much less good effect than faradization, which relieved the pain considerably and decidedly increased the molimen menstruale. The progress not being rapid enough to please me, and learning that various liquid caustic applications had been unsuccessfully employed before I took charge of her, I thoroughly cauterized the canal up to the fundus with the galvano-cautery, with a view of modifying the condition of the endometrium. This was done half-way between her periods twice in succession. The suffering was lessened very perceptibly, and she was thereafter kept upon tri-weekly faradizations of the uterus, with general and central galvanization. Her trouble steadily diminished, and in a year after commencing treatment she was almost entirely free from discomfort, with vastly-improved general health, and is now approaching the menopause with satisfaction to both doctor and patient. While I am willing to admit that the cauterization may have been an important factor, the failure of other caustic remedies in capable hands before I treated her, and the steady improvement under electricity alone, force me to believe her superb health thereafter,



as compared with her miserable condition previously, to be due without doubt to the treatment under consideration.

Electrization of the uterus or ovaries must be accomplished by *direct* applications. The plan usually adopted of sending the current through the abdomen by placing one rheophore upon the hypogastrium and the other over the sacrum is useless, the current traversing almost entirely the skin and parietal muscles, especially in faradization. The better method is to use a bifurcated conducting cord for one pole, to which two sponge-holders are attached, one of which is applied to the hypogastrium and the other to the lumbar spine.

The other pole is then applied, through suitable rheophores, to the exterior of the cervix, to the cervical canal at any desired point, to the fundus, or to the ovary, which can be reached near enough by pushing the instrument well up on either side of the cervix. In retroflexion or version, one rheophore may be applied through the rectum, and in antero-displacement it can be directed through the bladder; but I have never tried this latter method as yet. The instruments which I exhibit are well adapted to fulfil the various indications.

No. 1 is intended to confine the current to the uterus alone. It enters through the straight rod (which is insulated its entire length), escapes at its upper uninsulated point, and, passing through the body of the womb, returns through the large uninsulated ball at the cervix and the curved rod to the battery. The intra-uterine rod is movable, to suit long or short canals. No. 2 is a modified sound, insulated all except the curved intra-uterine part, and is used in connection with No. 5, which is an ordinary sponge rheophore. No. 3 is a ball electrode, intended for applications to the os uteri or ovary, and No. 4 is armed with a cup instead of the ball within which the cervix is engaged. The ball and cup only in either are uninsulated.

RHEOPHORES.

To secure good results, the batteries and accessories must be of *good make* and kept in *good order*. For the constant or galvanic current the Electropoion or Leclanche cell is preferable. A very serviceable battery of my own design was described in the *Medical and Surgical Reporter* of July 31, 1880, which can be made by any one of moderate mechanical skill at a very low cost, and illustrative cases of its utility have been published at different times during the last four years in that journal.

The faradic instrument may be of any manufacture in which smoothness of current is secured. To run the coil without sudden jars, large-quantity cells are demanded, such as the Grenet, which is at once simple, durable, and easily managed, or the Smee. No true polarity, of course, exists in induction-currents as found in ordinary apparatus, except in the elegant machine of Mottershead & Co., of Manchester, England. The difference of intensity in the initial and terminal currents of an inductorium, the first (during closure of the primary coil) being the weaker, and the second (whilst it is open) the stronger, has been ingeniously balanced by Kidder, of New York, and equal alternating currents secured; but the expense is in excess of the utility. Whilst the direction is a matter of no moment in faradism, galvanic currents, which are definite

in direction, appear to produce differing results according as they are ascending or descending. In neuralgic cases the rheotome is necessary, and more or less frequent reversion of the current heightens its value; while in congestion a steadily downward and uninterrupted flow is apparently the better plan. A most valuable but neglected method in neuralgia, not alone of uterine origin but of all types, is the use of *static* electricity, from the Holtz or Bertsch machine, which will often succeed after failure of all other proceedings.

Time will not at present permit any explanation of the *rationale* of electro-therapeutics as applied against dysmenorrhœa. There is, however, nothing empirical in this method of treatment, although superficial reasoning might lead to the idea that radically diverse conditions cannot be relieved by one and the same procedure. A little reflection will show that the action of many prominent drugs is at times diametrically opposite in effect; as, for instance, opium, quinia, and belladonna. At a future time this branch of the subject may be taken up.

The examples given of successful treatment can be multiplied, except only in the membranous variety. My object in this paper is not to decry other measures or to find fault: it is to enlist interest in a method at once simple, reliable, and effectual, though wofully neglected, probably because professional knowledge of electricity is largely confined to faradic currents from machines of doubtful construction and utility. Thus limited failure is inevitable, for galvanism is indispensable in many cases, in my belief, although such high authority as Duchenne has insisted on the availability of induction-currents in all instances and in all diseases for which electricity is employed.

The study of electro-therapeutics demands time and patience. All its branches must be explored and mastered in their details. Lack of care in looking after batteries is a common fault. They are allowed to rust and eat themselves up between-times, and, necessarily failing to work properly when needed, they are shortly consigned to oblivion, and electricity is thereafter a humbug! If more thought were given to the matter, the added therapeutic power thus obtained would make the physician the master of disease where now he is frequently impotent, and one of the most useful servants we possess—if not the best—would be, in the hands of intelligent gentlemen, a boon to the suffering, whilst at present it lies disgraced from being relegated to quacks and impostors.

246 North Twentieth Street.

A NEW MYDRIATIC.

BY HENRY S. SCHELL, M.D.,

Surgeon to Wills Hospital; Ophthalmic and Aural Surgeon to the Children's Hospital.

HOMATROPIN hydrobromate, manufactured by E. Mercke, of Darmstadt,* bids fair to be a very valuable addition to the resources of the ophthalmologist. Heretofore, in the treatment of iritis and other ocular complications, and in examination of difficulties of refraction, reliance has been placed almost wholly upon atropia and duboisia. Both of these are, indeed, invaluable, but both, nevertheless, have some properties which often render their use inconvenient, and even distressing.

Atropia sulphate, for instance, when used daily for some length of time, occasionally produces a granular condition of the tarsal conjunctiva, which inflames the cornea and sadly interferes with recovery. When used to suppress the accommodation, during an inquiry into the state of the refraction, the effects of a single application often last for ten days, and, in consequence of the dilatation of the pupil and the inability to focus the eye upon near objects, the patient remains for that length of time practically blind so far as reading, writing, or other close occupation is concerned, and subject also to the well-known disagreeable feelings attendant upon the entrance of a flood of light into the unguarded eye. In addition to this, so large a quantity of the drug is often required to produce the desired local effect that the general system becomes involved, and the patient suffers from constant dryness of the throat and mouth, flushing of the face, acceleration of the circulation, feelings of languor, and even from nausea and vomiting.

Duboisia sulphate is more convenient for use in examinations of the refraction, as its action is quicker and its effects sooner over. These last only about one-

* Imported by Henry C. Blair's Sons & Co.

half as long as those of atropia. But in the use of duboisia, also, we are often obliged to employ so much locally that the patient is made to feel giddy, sometimes to such an extent that it is unsafe to let him go into the streets alone for an hour or more.

Homatropin promised so much better results that I was led to make with it the following series of experiments:

Exp. I.—W. T., aged 43, had been accustomed for a year or two to wear $+\frac{1}{42}$ for reading or writing. Left eye tested. With $+\frac{1}{42}$ can read $1\frac{1}{2}$ Sn. at 11″. Diameter of pupil 3 mm. 9.16 A.M., instilled two drops of a four-grain solution of homatropin hydrobromate. Patient complained that it produced a slight stinging sensation. There is a little reddening of the conjunctiva.

9.27 A.M., instilled two drops.

9.35 A.M., with $+\frac{1}{42}$ reads No. 3 Sn. at 14″. Pupil 5 mm.

9.40 A.M., with $+\frac{1}{42}$ reads No. $3\frac{1}{2}$ Sn. at 14″. Pupil 8 mm. With $+\frac{1}{30}$s ⊃ $+\frac{1}{30}$c, axis 90°, $V = \frac{20}{XV}$?

The next day, at 9 A.M., with $+\frac{1}{42}$ read No. $1\frac{1}{2}$ Sn. at 14″. Pupil 4 mm. Reported that he could see to read and write with comfort at 2 P.M. of the day before.

Exp. II.—M. F., aged 18, a strong, healthy girl. Ophthalmoscopic examination through the undilated pupil disclosed hypermetropia of at least $\frac{1}{16}$. Right eye, $V = \frac{20}{XXX}$? Reads D .50 Sn. from 13 to 40 cm. Pupil 3 mm.

11.40 A.M., instilled two drops of homatropin hydrobromate, four-grain solution.

11.45 A.M., two drops.

11.50 A.M., reads D .50 Sn. from 17 to 48 cm. Pupil 3 mm.

11.55 A.M., two drops.

12 M., reads D .50 Sn. from 18 to 42 cm.

12.5 P.M., two drops.

12.10 P.M., cannot read. Pupil 6 mm. $V = \frac{20}{C}$.

12.15 P.M., two drops.

12.20 P.M., pupil 7 mm. $V = \frac{20}{C}$?

12.25 P.M., two drops.

12.30 P.M., pupil 8 mm. Slight congestion of conjunctiva. $V = \frac{20}{CC}$.

12 35 P.M., two drops.

12.45 P.M., two drops. Patient complains of some smarting in the eyes.

12.50 P.M., $V = \frac{10}{CC}$. With $+\frac{1}{10}$s $V = \frac{20}{XXV}$.

The next day, at 9.30 A.M., she read D 1.25 Sn. at 15 cm.

The following day two drops of an eight-grain solution of atropia sulphate were instilled. An hour after $V = \frac{10}{CC}$. With $+\frac{1}{9}$ $V = \frac{20}{XXV}$.

This case demonstrated the difficulty of entirely overcoming the accommodation, in high degrees of hypermetropia, with a weak solution of the mydriatic. It is evident, however, that sufficient time was not allowed to elapse after the final instillation before the test was made of the total hypermetropia. It is probable that twenty minutes later the testing would have agreed with that determined two days later under atropia.

Exp. III.—Miss C. V. C., aged 27, a weak and nervous lady, with a quick, irritable pulse. Right eye, $V = \frac{20}{XXXV}$. Left eye, $V = \frac{20}{XXV}$. Reads $1\frac{1}{2}$ Sn. at $6\frac{1}{2}$″, nearest point of distinct vision. Pupil 4 mm. Experiment made with an eight-grain solution of homatropin. 9.46 A.M., one drop put in each eye; 9.48, one drop each; 9.50, repeat; 9.52, repeat. No smarting complained of. Conjunctiva not reddened. Dilatation of pupil commenced at 10 A.M. 10.8, pupil 7 mm. Smallest type which can be read, No. $3\frac{1}{2}$ Sn.; near point 11″. 10.10 A.M., reads $1\frac{1}{2}$ Sn. with $+\frac{1}{10}$ at 8″; therefore Ac. $\frac{1}{40}$. 10.20, pupil 8 mm. $V = \frac{20}{XXXV}$.

Right eye, $+\frac{1}{36}$s ⊃ $+\frac{1}{48}$c, axis 90°, $V = \frac{20}{XV}$.

Left eye, $+\frac{1}{42}$s ⊃ $+\frac{1}{48}$c, axis 90°, $V = \frac{20}{XV}$.

She appeared quite well when she left my office, at the close of the experiment, and denied feeling any dryness of throat or other unpleasant symptoms. She did not reappear, however, until the day but one following, when she stated that she had suffered much from dryness of the throat and lips, headache, and nausea during the entire interval. As her menses, however, had also returned, it is possible that some of the symptoms may have been natural enough under the circumstances. She stated that she could see to read the day after the eyes had been tested, and, upon examination, I found that she could again easily read No. $1\frac{1}{2}$ Sn. at $6\frac{1}{2}$″.

Exp. IV.—B. H., aged 17, a muscular young man. The ophthalmoscope showed a high degree of compound myopic astigmatism. Near point for No. 1 J. was 3″. Pupils 3 mm. Four drops of an eight-grain solution were placed in each eye at 8.45 A.M. At 8.55 his pupils measured 4 mm., and his near point had receded to 6″. At 9.15, pupils 8 mm.; near point 6″. The error in refraction of the right eye was found to be corrected by $-\frac{1}{7}$s ⊃ $-\frac{1}{18}$c, axis 165°, $V = \frac{20}{XXXV}$; left eye by $-\frac{1}{8}$s ⊃ $-\frac{1}{14}$c, axis 180°, $V = \frac{20}{XXXV}$.

In this instance the weak ciliary muscle quickly gave way under the influence of the mydriatic. The iris responded less readily. No unpleasant local or general effects were observable.

Exp. V.—A. M., a healthy girl of 15. She had suffered from asthenopia, and I had

examined her right eye a few days before under atropia, with the result of determining an error of refraction, which was accurately corrected by $-\frac{1}{48}$c, axis 90°. Upon this occasion the left eye was examined. V = $\frac{20}{XX}$. Near point for No. 1 J. 5 in. Pupil 5 mm. 9.40 A.M., two drops of eight-grain solution; 9 42, two drops; 9.50, reads as before; pupil 6 mm. Slight congestion of conjunctiva and sense of smarting in the eye. 10.10 A.M., pupil 7 mm.; reads $2\frac{1}{2}$ Sn. not nearer than 8″; V = $\frac{20}{XX}$. Repeat drops. 10.20 A.M., same condition. Repeat drops. 11 A.M., reads No. 12 J. at 11″; V = $\frac{20}{XX}$. Repeat drops. 11.30 A.M., V = $\frac{20}{XXV}$. With $+\frac{1}{60}$c, axis 180°, V = $\frac{20}{XII}$. The next morning, at nine o'clock, it was found that she could again read $1\frac{1}{2}$ Sn. readily, and that she had suffered no inconvenience from the drug.

Exp. VI.—W. S., a gentleman of 31; looks delicate; an artist by profession. Had suffered from asthenopia, in consequence of which I had examined his right eye a week previously, under the influence of duboisia sulphate, and found an error of refraction, which was corrected by $+\frac{1}{60}$ s. ⊃ $+\frac{1}{60}$ c. axis 90°. V = $\frac{20}{XII}$. Left eye, V = $\frac{20}{XXX}$. Near point for No. 1 J. at 5″. Pupil 5 mm. 10.05 A.M., instilled four drops of an eight-grain solution of homatropin. 10.10, repeat. No smarting or congestion of conjunctiva. 10.30, cannot read No. 1. Reads $3\frac{1}{2}$ Sn. at 24″. Pupil 7 mm. V = $\frac{20}{XXXV}$ with $+\frac{1}{42}$ c. axis 105°. V = $\frac{20}{XII}$. 10.45, repeat instillations (four drops). 11.15, same results. The next day at 9 A.M. he read $1\frac{1}{2}$ Sn. at 13″ with difficulty, No. 2 with ease at 12″, with left eye. Pupil 6 mm. He complains that he was wakened in the night by neuralgic pain in the left eye, extending over the temporal region of the same side. The pain had continued, with increasing intervals of relief, to the time of his visit, when there was but little left. He had had a similar attack in the right eye after the use of the duboisia, but not so severe. On the following day he reported that the pain had quite disappeared by 2 P.M. of the day previous.

The large quantity—twelve drops—used in this case probably caused the attack of pain,—an attack which may hint at a glaucomatous tendency in the individual, and, at any rate, serves as a warning note in that direction. There were, however, none of the other signs present which characterize the glaucomatous condition.

Owing to the inconvenience in practice connected with the use of so large a number of drops in the eye, the strength of the solution was doubled, and the following experiments were made with a liquid containing sixteen grains to the fluidounce of distilled water.

Exp. VII.—L. W., a girl of 8 years. Has difficulty in studying on account of her eyes. V = $\frac{20}{XXV}$ in each. Examined by means of the undilated pupil, the ophthalmoscope shows a hypermetropia of at least $\frac{1}{10}$ in each. The smallest print she can read is $5\frac{1}{2}$ Sn., near point, with both eyes, 4″. Pupils 4 mm. 4.15 P.M., one drop in each eye. 4.23, repeat. No smarting or suffusion of the conjunctiva. 4.45, pupils 8 mm. V = $\frac{6}{CC}$ each; with $+\frac{1}{7}$ V = $\frac{20}{XXV}$. As there was a possibility that this was not the total hypermetropia, one more drop was put in each eye at 5 P.M. 5.30, pupils as before, with $+\frac{1}{6}$ V = $\frac{20}{XXV}$ in each eye. There was no dryness of throat or other unpleasant symptoms, although this child received a fifty per cent. larger dose of homatropin than the lady mentioned in Exp. III. At 9.25 A.M. next day she could again read $5\frac{1}{2}$ Sn. at 6″ with the naked eyes. V = $\frac{20}{XXV}$. Pupils 7 mm. To make assurance doubly sure, I instilled one drop of an eight-grain solution of atropia sulphate in each eye, and examined them both again at the expiration of an hour, with the same result as that obtained on the previous day.

Exp. VIII.—W. G., a robust gentleman of 45 years. Eyes had commenced to fail in reading. Reads $1\frac{1}{2}$ Sn. at 15″ with both eyes. Pupils $2\frac{1}{2}$ mm. Right V = $\frac{20}{XVIII}$. Left V = $\frac{20}{XXV}$. 10.7 A.M., put two drops in each eye; followed by slight congestion of the conjunctiva. 10.19, repeat drops. More congestion. 10.22, reads $3\frac{1}{2}$ Sn. at 24″. 10.25, reads $6\frac{1}{2}$ Sn. at 24″. 10.45, right V = $\frac{20}{LX}$. Left V = $\frac{20}{XC}$. Right $+\frac{1}{36}$s. V = $\frac{20}{XII}$. Left $+\frac{1}{48}$s. ⊃ $+\frac{1}{72}$c. 75° V = $\frac{20}{XII}$. Pupils 6 mm., and immovable. 11 A.M., one drop in both, to ascertain if any hypermetropia is still latent. 11.30, results as before. At 10 A.M. next day irritation of conjunctiva had disappeared. With correcting-glasses reads $1\frac{1}{2}$ Sn. at 15″. Pupils 5 mm. Right eye V = $\frac{20}{XXV}$. Left eye V = $\frac{20}{XXX}$.

Exp. IX.—B. J., a girl of 14 years. Has difficulty in reading. Right eye V = $\frac{20}{LX}$. Left eye V = $\frac{20}{C}$. Reads nothing smaller than $2\frac{1}{2}$ Sn. Near point 5″. Pupils 6 mm. 9.26 A.M., one drop in each eye. 9.28, repeat. 9.30, repeat. 10.02, right eye V = $\frac{20}{C}$. Left V = $\frac{20}{CL}$. Pupils 8 mm. Right eye

with $+\frac{1}{30}$s. ⊃ — $\frac{1}{18}$c., axis 180° V = $\frac{20}{XXV}$. Left eye with $+\frac{1}{20}$s. ⊃ — $\frac{1}{8}$c., axis 180° V = $\frac{20}{XXV}$. 10.40 A.M., applied one more drop to each eye. 11.15 A.M., refraction as before. No dryness of the throat. No congestion of conjunctiva.

The next day, at 9 A.M., she read 2½ Sn. at 6″ with the unaided eyes. Pupils 6 mm. Has had no dryness of throat or other discomfort.

Exp. X.—M. F., a school-girl, 15 years of age. Right eye V = $\frac{20}{XX}$. Reads D. 1 Sn. at 9.64 cm. as near point. Pupil 3 mm. A four-grain solution used; seventeen drops put in the eye, at the rate of one per minute. Smarting and congestion of conjunctiva produced.

The accommodation began to yield with the eighth drop,—that is to say, at the end of eight minutes. Total suppression was not obtained, the amount of the mydriatic used not being sufficient. The pupil attained its maximum dilatation, 8 mm., in twenty-three minutes after the first drop was applied.

Exp. XI.—This experiment was made with the last-mentioned patient, and two days later than the previous trial. Its object was to determine how soon after complete paralysis the ciliary muscle commenced to regain its powers. A four-grain solution was used. Two separate instillations, of ten drops each, were made in the right eye, the first at 7 A.M., and the other at 7.30 A.M. 8 A.M., V = $\frac{20}{L}$. Ac. = O. H. = $\frac{1}{36}$. 9 A.M., V = $\frac{20}{L}$. 10.30 A.M., V = $\frac{20}{XL}$. 11 A.M., V = $\frac{20}{XXX}$. 2 P.M., V = $\frac{20}{XXV}$. 6 P.M., V = $\frac{20}{XX}$.

The accommodation, therefore, commenced to reassert itself in three hours from the time of the last instillation, and was fully restored in ten hours and a half, for at six o'clock she could read D. 1 Sn. at 10 cm.

These experiments appear to justify the following conclusions:

1. Homatropin hydrobromate is not well adapted to the treatment of inflammatory or traumatic affections of the eye, on account of the conjunctival irritation it produces.

2. It is especially adapted to the production of that temporary dilatation of the pupil and paralysis of the ciliary muscle which is so often required in examining the condition of the refraction.

3. The best solution to use is one containing sixteen grains to the fluidounce of distilled water. From one to five drops of such a solution may be required to produce the desired effect, according to the strength and activity of the ciliary muscle.

4. Under the influence of a full dose the pupil attains its maximum dilatation in about twenty minutes.

5. With a full dose the accommodation begins to fail in about ten minutes and is usually totally suppressed in a half-hour, although exceptional cases may require an hour. This total suppression lasts about three hours; the accommodation then gradually recovers itself, and is fully in action again at the end of from ten to thirty hours from the time of the last instillation.

6. The local action of the mydriatic is not accompanied by any unpleasant effects upon the general system.

ON SCLEROTOMY IN GLAUCOMA.

BY M. LANDESBERG, M.D.,
Philadelphia.

OF all operative procedures which have been devised in order to supplant iridectomy in glaucoma, sclerotomy is the only one which deserves our consideration. By sclerotomy we are to understand a distinct operation, which consists in making a section of the sclera at the sclero-corneal border, without excision of the iris, avoiding the prolapse of the latter. Sclerotomy I have performed with section in the sclero-corneal border, as if about to make a scleral flap for linear extraction of catarrh. In the majority of cases I left a scleral bridge; in some instances the section was completed and a conjunctival flap formed. The section was made with Von Graefe's knife, in the most cautious manner, in slow, drawing motions of the knife, which was cautiously withdrawn, allowing the aqueous humor to escape, but very slowly. A compressive bandage on both eyes was applied until the wound was perfectly closed. Instillations of extract of calabar or of eserine were freely used, both before and after the operation, in order to bring about the utmost contraction of the pupil. In no case have anæsthetics been administered.

Of the thirty-five cases of glaucoma in which I performed sclerotomy, there were

7	cases of	glaucoma simplex;
10	"	" subacutum;
2	"	" acutum;
1	case of	" fulminans;
5	cases of	" inflammatorium chronicum;
10	"	" absolutum.

The result of the operation in the different forms of glaucoma was as follows:

A.—GLAUCOMA SIMPLEX.

(The most insidious form, which sets in and takes its course without any inflammatory symptoms; a form in which iridectomy also often fails to check the morbid process.)

In one case the primary result was very favorable. Intraocular pressure and pupil became normal, and vision increased from $\frac{15}{50}$ to $\frac{15}{30}$; but after three months glaucomatous attacks again set in.

In another case, in which iridectomy made five months before was of no avail, sclerotomy succeeded in checking the morbid process; but intraocular pressure remained pathologically increased, and vision did not improve.

In two cases intraocular pressure became normal, but pupils remained dilated, and vision decreased from $\frac{15}{100}$ resp. $\frac{15}{200}$ to $\frac{10}{200}$ resp. $\frac{5}{100}$.

In one instance the operative intention did not succeed. Prolapse of iris occurred during section, which necessitated iridectomy.

In two cases there was complete success. Intraocular pressure became normal, pupils of good reaction, and vision increased from $\frac{15}{70}$ resp. $\frac{15}{40}$ to $\frac{15}{50}$ resp. $\frac{15}{30}$.

B.—SUBACUTE GLAUCOMA.

In one case sclerotomy caused immediate decrease of intraocular pressure, but acute glaucoma set in during the healing process, which necessitated iridectomy.

In two cases intraocular pressure did not decrease consequent upon the operation. Hemorrhages repeatedly occurred; wound burst, causing prolapse of iris. Iridectomy checked the morbid process in one instance; in the other, the final issue was phthisis of the eyeball.

In one case the result was very favorable. Intraocular pressure became almost normal, and vision increased from $\frac{15}{100}$ to $\frac{15}{70}$.

In two cases, of which in one instance iridectomy had been made six weeks before without any avail, a small prolapse of iris occurred during section, the reposition of which, however, succeeded perfectly. The result was very good. Intraocular pressure became normal, and vision increased from $\frac{5}{100}$ resp. from counting fingers at 9′ to $\frac{10}{100}$ resp. $\frac{20}{70}$.

In two cases prolapse of iris occurred during section, the reposition of which did not succeed. Iridectomy was performed.

In one case, in which the glaucomatous process reappeared in spite of two iridectomies, sclerotomy brought perfect success. Intraocular pressure became normal, and vision increased from counting fingers at 5′ to $\frac{5}{200}$.

In one case, in which I had performed iridectomy for acute glaucoma eleven months before, sclerotomy gave a perfect result. Intraocular pressure became normal, and vision increased from $\frac{10}{200}$ to $\frac{20}{70}$.

C.—ACUTE GLAUCOMA.

In a case of acute glaucoma consequent upon serous iritis, sclerotomy brought perfect recovery, with restitution of normal vision.

In a case of genuine acute glaucoma, sclerotomy was followed by immediate improvement in the condition of tension and vision, but from the third day of the operation glaucomatous attacks set in again. Iridectomy was of no avail. Iridocyclitis developed, evolving into phthisis of the eyeball.

D.—GLAUCOMA FULMINANS.

(A rare form, which breaks out suddenly without any premonitory symptoms, and in which the course is so rapid that vision may be entirely lost within a few hours,—even within a few minutes.)

This form was observed in a patient consequent upon instillations of a few drops of atropia into the eye. Sclerotomy, performed on the day of the occurrence, brought perfect restitution *ad integrum.*

E.—CHRONIC INFLAMMATORY GLAUCOMA.

In four cases the course of the operation was normal. In one case a small prolapse of iris occurred during section, the reposition of which succeeded perfectly. Intraocular pressure became normal in three cases, and remained slightly increased in two cases. Vision improved

from	counting	fingers	at	5′	to	15′;
"	"	"	"	3′	"	20′;
"	"	"	"	5′	"	15′;
"	"	"	"	3′	"	6′;
"	"	"	"	$\frac{5}{200}$	"	$\frac{10}{100}$.

F.—GLAUCOMA ABSOLUTUM.

In all these instances vision was irreparably lost, and sclerotomy made only for the

purpose of checking the further progress of the disease, viz., to abate the irritative symptoms and to cause decrease of the intraocular pressure.

Immediate perfect success was obtained in six cases, in three cases of which iridectomy had been made two or three years before without checking the morbid process. Symptoms of irritation subsided, and intraocular pressure became normal.

In two cases, of which one showed ribbon-shaped opacity of the cornea, the inflammatory symptoms subsided entirely, but tension remained slightly increased.

In one case the normal course of operation was followed by violent symptoms of irritation and by frequent intraocular hemorrhages. The wound was forced open, and prolapse of iris took place. Iridectomy broke the acme of the morbid process.

In one instance sclerotomy had to be repeated after seven weeks, when the glaucomatous attacks, which had been checked by the first sclerotomy, reappeared. The final result was good. All symptoms of irritation subsided. Intraocular pressure became normal.

The facts show that sclerotomy shares with iridectomy the faculty of diminishing the intraocular pressure, checking the glaucomatous process, and securing a certain restitution of the function of the eye. Certainly, this aim is not always attained, and sclerotomy shares with iridectomy its failures. The very great advantage which sclerotomy has over iridectomy consists in this, that by leaving the iris intact the operation is not accompanied with so many drawbacks (impairment of vision, dazzling, etc.) as present themselves in iridectomy. Which *rôle* sclerotomy will play in the therapeutics of glaucoma—whether it will totally supplant iridectomy or limit only the indications for the latter operation—the future alone can tell, when a truer insight into the nature of glaucoma will enable us to decide upon the best method of treatment.

For the present, summing up the results of my observations, I do not hesitate to put forth sclerotomy as the first indication in the following conditions:

1. In glaucoma absolutum.

2. In secondary glaucoma, and in glaucoma-like conditions of the eye, as observed in iritis, serous choroiditis, in certain forms of keratitis, etc.

3. In all cases of glaucoma in which iridectomy had been made and the reappearance of the glaucomatous process necessitates the repetition of the operative procedure.

1912 Arch Street.

THE RESULTS OF A TEST FOR COLOR-BLINDNESS AT GIRARD COLLEGE.

BY W. S. LITTLE, M.D.

DURING April, 1880, the boys at Girard College were tested by me for color-blindness; ages ranging from 6 to 18 years; 845 boys were examined. The test employed was Holmgren's method with colored worsteds. Of those that were found defective a re-test was made to confirm the work, and the same result was attained. This is hardly necessary, as it brings the persons who are found defective into too much prominence among their associates. One boy was tested four times, failing each time, his teacher being hard to convince, as he gave the proper names to the color exhibited in the class-room, showing that when a color is held up to a class, with the statement that it is a given color, each person associates the name with the sensation it produces, and yet it may appear differently to the individuals observing it.

Color-blindness is divided, according to the Young-Helmholtz theory, into—

1. Total color-blindness;
2. Partial color-blindness.

Partial color-blindness is divided into—

1. Complete color-blindness;
2. Incomplete color-blindness.

Complete color-blindness is divided into—

1. Red-blindness;
2. Green-blindness;
3. Violet-blindness.

Incomplete color-blindness exists where an inferior excitability for all three elements, red, green, or violet, or for one in particular, is present.

The condition existing under partial color-blindness, complete or incomplete, where red- and green-blindness is found, is the subject of much investigation at present, in order to arrive at the possible average of its presence among men, so as to avoid the dangers to which it exposes travellers, as red and green colors by day and night are employed on railroads to signify danger and safety, and also on

vessels at night to indicate their position. Army and navy orders are sometimes required to be conveyed by means of colored signals, and the knowledge of any color-defect is also important to youth in the selection of a trade or avocation in life. "Color-Blindness, its Danger and Detection," by Dr. Jeffries, goes fully into the whole subject. The result of examinations made thus far shows about 1 in 25 among males color-blind to a greater or less degree.

The result of the test at Girard College is as follows:

Boys examined, 845. Complete and incomplete, 38; 4.497 per cent. Complete, 29; 3.431 per cent. Red, 17; 2.011 per cent. Green, 12; 1.420 per cent. Incomplete, 9; 1.066 per cent.

The presence of 4.497 per cent. is little above the average.

There were three cases of apparent indifference to all colors, their ages being respectively 6 years. A general deficiency in everything besides color prevents me from quoting them as cases of total color-blindness. I shall test these boys when they have increased in years and ability. I also found nine cases of violet-blindness and three cases of yellow-blindness.

Two brothers were color-blind. I have been unable to learn concerning the other members of this family.

There were in all 53 with color-defect, but only 38 are quoted as belonging to the dangerous element of color-blindness. The acuity of vision of the color-blind was tested, though the one is independent of the other. Of the 38 cases, 17 had full acuity of vision, and 21 were defective.

Of the 53 (almost all forms of color-defect), 24 had full acuity of vision, and 29 were defective. The examination was made without mydriasis.

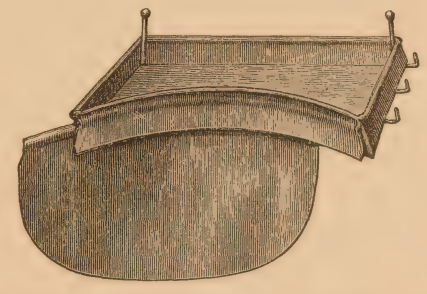
I examined many of the color-blind with each eye separately, and of those examined found color-blindness for both eyes. As has been stated, it is possible to be color-blind in one eye and not in the other.

I am much indebted to President Allen, of Girard College, and the officers of the institution, for the facility given me in conducting the test; also to Dr. R. J. Hill, U.S.A., for his assistance.

The boys, on leaving the institution, are sought for in various trades and in the merchant marine, and a knowledge of their defect would prevent them from making a choice where the want of full color-sense might stand in the way of their success.

The engraver's art affords a successful field for the color-blind, where shading is necessary, and, as they are very sensitive to shade, the defect can be made useful to art.

219 South Seventeenth Street.



A PORTABLE SURGICAL TRAY AND A NEW UTERINE TENACULUM.

BY W. W. KEEN, M.D.,

Surgeon to St. Mary's Hospital, Philadelphia.

A PORTABLE SURGICAL TRAY.

DURING an operation surgeons are frequently annoyed by losing an instrument in the folds of a blanket or by its falling on the floor, where it may be spoiled by losing its point. Moreover, even a small table alongside is often in the way, especially when many assistants are needed, as, for instance, in operations in the uterus, when one assistant must hold each leg, another uses the sponges, and another, it may be, holds a tenaculum. To obviate some, at least, of these disadvantages, I have devised a portable surgical tray, to be fastened to the body of the operator. The

material is stout tin. It is ten inches long, four and a half inches wide in the middle, and six and a half at the ends. Its sides incline one-fourth inch inward. It is one and one-fourth inches deep. At the two front corners two wire posts project one-half inch above the tray, to prevent instruments longer than the tray from falling out; the point being in the tray, the post catches the handle. At each end are three hooks of wire each doubled upon itself, so as to make a smooth end. On these scissors, dressing-forceps, ligatures, etc., can be hung. The piece *a*, as is seen, slides horizontally, and can be thus easily re-

moved and replaced. This is not a necessity, but is only to facilitate packing the tray in a smaller space. For hospital use *a* can be soldered firmly to the tray. To fix it to the body a strap two and a half inches wide is buckled over the vertical piece *a*, and to prevent the straps from sliding down there is a slight horizontal shelf of tin one-quarter inch wide in front of *a*. For many operations such a tray is not only useless, but would be seriously in the way; but for most gynæcological and other operations, when the operator is seated, as in operations on the ear, nose, throat, etc., it will be found of great use. When operations require different sets of instruments at different steps, the tray will be convenient to hold those needed at the moment. In hospitals, too, unless Morton's hospital dressing carriage is used, the tray will be very useful in passing with the residents from bed to bed. It has been made for me by Austin & Opdyke, 1705 Chestnut Street, and costs $1.50 for the tray alone.

NEW UTERINE TENACULUM.

When a tenaculum is used, either the operator is deprived of one of his hands for other purposes, or else an assistant must use it, in which case his hand is often very much in the way. This tenaculum is one and a half inches long, and has two hooks. Of course the size of the instrument and the number of hooks can be varied at will. The peculiarity of the instrument is that it has no handle. Instead of this it has an eye, which is threaded with wire. The tenaculum is then inserted into the uterine lip by means of dressing or other forceps, the wire is drawn right or left, and fastened by winding it around some suitable part of the speculum. If such suitable projecting part be only on one side, a slight groove can be nicked in the edge of the speculum at any point and the wire be passed first through the groove. By this means both of the surgeon's hands are free, no assistant is needed, and the needed space is not narrowed by any band.

THE Provident Dispensary at Leicester, England, contains 25,000 members, and has an annual income of $20,000.

DR. J. E. MICHAEL has succeeded Dr. Miles as professor of anatomy in the University of Maryland.

TRANSLATIONS.

SPINA BIFIDA IN ITS ETIOLOGICAL AND CLINICAL RELATIONS. — A. Wernitz (*Inaug. Diss., Dorpat;* from *Cbl. f. Chir.*, 1880, p. 506), as a result of his studies and experience, comes to the following conclusions:

Spina bifida, better known, according to its degree, as rachischesis, meningocele, myelocele, or hydro-meningocele, is one of the commonest congenital deformities, one infant in every thousand showing it (in Germany). It is rarely the cause of difficult labor. Of ninety children with spina bifida, not operated upon, the greater number died within the first week, only twenty passing the age of five years. In his dissertation, Wernitz speaks of the hereditary relationships, the various forms, and the seat of the deformity. As regards the latter point, the author gives a tabular description of two hundred and forty-five cases. From this it appears that the lumbar and sacral regions were affected in one hundred and twenty-seven cases, the sacrum alone in fifty-three cases, while the affection is only rarely met with in other regions of the spine. The author gives an account of the nature of the trouble under its various forms, together with the complications which may arise with hydrocephalus, anencephalus, congenital club-foot, etc. He concludes this portion of his subject by describing anterior spina bifida in which the bodies of the vertebræ show openings. He also speaks of the pathological anatomy of these tumors, the normal anatomy of the sacral region and its relations with the spinal cord, from which it appears that the former often extends deeper in spina bifida than in the normal condition. The cause for this is to be sought in the circumstance that the spinal cord, which in the two-months' fœtus fills the entire spinal cavity, and in spina bifida adheres to its membranes in the neighborhood of the sacrum, is stretched by the growth of the vertebral column. By the simultaneous pressure of the tightened membranes in the upper border of the defect in the vertebræ, the opening may probably widen above, while diminution of pressure causes the vertebræ which touch it to tend inwards. With regard to the cases where the spinal cord is entirely wanting, Wernitz inclines to the opinion that while the medullar portion has developed

properly the cord has not developed. As to the cerebro-spinal fluid, the question whether the hydrostatic pressure is increased or not is settled that in some cases an increase is observed. Communication exists between the central canal of the cord, the ventricles and subarachnoidal spaces of the brain, so that a tendency inward of the spina bifida tends to give rise to hydrocephalus.

The author's description of the diagnosis and prognosis is given in the original at too great length to cite: it may be noted, however, that certain cases are mentioned in which tumors of the sacral region have been extirpated, having been taken for lipomata, and which turned out to be meningoceles covered with fat. Under the head of etiology, the author, after going extensively into the developments of the spine and spinal cord, and comparing the normal condition with that found in preparations of diseased tissues, comes to the conclusion that an arrest of development is evident which leads to the defect in the bony canal and the formation of the meningocele. As to treatment, compression, ligature, puncture (alone and with injections), and excision are all fully described, together with a case of Koch's, in which excision, followed by a plastic operation, cured the defect entirely. Statistics of the various operations are added, by which it appears that puncture, with injection of iodine, is the most successful.

Stricture of the Rectum.—From a review of Dr. Ceccherilli's work on this subject, in the *Jour. de Sci. Méd. de Louvain* (1880, p. 357), we learn that this author rejects strongly the method of forced dilatation proposed by Simon, of Heidelberg, above all as a diagnostic means. He prefers digital examination, or, if this is insufficient, the sound or the speculum. With regard to spasmodic stricture of the rectum the author concludes, after a careful examination of testimony, that the affection is to be regarded as a rectal neuralgia, not to be confounded with that painful spasm which occurs during defecation when the rectal bolus distends an anal fissure. The author does not absolutely deny the existence of idiopathic spasmodic stricture, although it cannot be affirmed in any given case that some slight superficial fissure may not exist in a fold of the anal mucous membrane. In the chapter devoted to the pathogenesis of hyperplastic strictures caused by syphilis, he concludes, after a careful examination of the opinion of well-known authors, that these are simply the result of a gumma. In a valuable chapter on therapeutics the author expresses little confidence in cauterizations, and colotomy he objects to entirely. Between the two ordinary means of treatment, incision and dilatation, he prefers internal incision and adopts rapid dilatation.

Esmarch's Bandage in the Removal of Fibrous Abdominal Tumors. — At a recent meeting of the Académie de Médecine (*Le Progrès Méd.*, 1880, p. 649), M. Labée read a communication relative to a modification of the operative procedure of hysterotomy applied to fibrous tumors (exsanguification of the tumor). Gastrotomy for the removal of fibrous tumors of the uterus is now a well-established operation, and M. Labée did not attempt to describe it, but simply called attention to an important modification which he has introduced into the operative procedure. The quantity of blood contained in these enormous tumors of the uterus is always considerable, and the loss of blood consequent upon the ablation of the tumor is a factor the importance of which it is impossible not to recognize, especially when it is considered that the women from whom these tumors are removed are always in a state of advanced cachexia. M. Labée conceived the idea of using Esmarch's bandage in these cases, with the view of pressing back into the general circulation as much as possible of the blood contained in the tumor, that this might be retained in the economy. The first patient on whom the plan was tried presented a rather hopeless prospect, being in a deplorable condition before the operation. She succumbed to septicæmia six days after its performance. But M. Labée was able to satisfy himself that the enormous fibroma on which compression had been practised was completely deprived of blood, more than a litre of blood having thus been restored to the system. M. Labée suggests that long needles or skewers should be fixed in the walls of the tumor at proper points to prevent the bandage from slipping off.

Treatment of Varices by Perivenous Injections.—This method was introduced by Dr. Marc Sée. M. Chabert, in a thesis recently published (*Bull. Gén. de*

Thérap., vol. ii., 1880, p. 90), gives the following points in the procedure. A hypodermic syringe with a very fine trocar is employed, the fluids ordinarily used being liquor ferri perchloridi diluted to $\frac{1}{30}$ and mixed with a little water, or else alcohol of 90°. The patient having been confined to bed for several days previously, the skin over the vein is pinched between the thumb and finger, so as to facilitate the introduction of the trocar, which should be made to penetrate the perivenous cellular tissue. Then one to three drops of the iron solution or one to two drops of alcohol are injected at a distance of five to twelve millimetres from the vessel (a quarter to half an inch). Several injections may be made around the varicose vein at different points. Two, or even one, however, will usually be sufficient. When the injection is made, the patient feels a sharp pain at the point of puncture; this pain occurs again for some days after, if not spontaneously, at least on pressure. In twenty-four to forty-eight hours the course of the vein becomes hard, painful to the touch, and slightly swollen. Dr. Chabert concludes as follows. 1. Varices are sometimes sufficiently serious, even when uncomplicated, to necessitate curative treatment, especially in the case of working-people, who are sometimes completely disabled. 2. When varices are complicated, especially by ulcers, the necessity for treatment is even more urgent. 3. Among the methods of treatment ordinarily employed, cauterization appears to have been most successful; but intravenous injections of perchloride of iron, to which may now be added perivenous injections of the same, appear to offer every chance of success, with much less danger to the patient. 4. This plan of treatment, however, needs to be followed out and the results carefully noted, as enough is not yet known of the remote results.

ARNICA.—From physiological experiments made by M. Planat, he was led to use arnica in acute superficial inflammations, such as erysipelas, angina furuncle, etc., and was so successful that he believes that arnica will abort furuncles with the most extraordinary promptness. He excepts, however, that form of furuncle which he denominates diabetic furuncle. The remedy is prepared and applied in the following manner:

Extract of fresh arnica flowers, ten grammes; honey, twenty grammes; powder of lycopodium, sufficient to make a paste of proper consistency to spread.

This is spread upon adhesive plaster and applied to the furuncle. Renew the plaster every twenty-four hours. Internally, give twenty-five to thirty drops of the tincture of arnica every two hours. The effect, M. Planat says, is so rapid as to leave no doubt of the special value of the remedy. —Bouchardat: *L'Abeille Médicale.*

OXALIC ACID AND OXALATE OF POTASSA IN DIPHTHERIA.—As soon as the diphtheritic deposit is perceived, Cornilleau directs the following prescription to be taken:

℞ Oxalic acid, gr. xxiii;
Infusion of green tea, ℥iv (Troy);
Syrup of bitter orange peel, ℥i (Troy).

A teaspoonful every three hours. A tea prepared by adding five ounces of fresh sorrel leaves to a quart of water, a half-cupful, or less, according to the age of the patient, to be taken at a time, every hour or so, is also advised.

After the third day of treatment a marked improvement in the condition of the patient has been observed, and convalescence generally occurs at the end of the first week. When the disease assumes the intermittent form, Dr. Cornilleau prefers the bromohydrate of quinia, given hypodermically. A tonic regimen should be maintained, milk, broth, wine, coffee, etc., being freely allowed. — *L'Abeille Médicale.*

ACTION OF COLLODION ON THE TEMPERATURE.—Dr. Raducan (*Bull. Gén. de Thérap.*) has investigated the influence excited by the application of flexible collodion to the surface. He finds that applied to the limbs it does not alter the central temperature, but applied over the peritoneum or pleura a notable lowering of the central temperature is at once obtained. There is no question that the influence of these applications in phlegmasiæ of the extremity is very favorable.

APPLICATION FOR CHANCRE.—

℞ Perchloride of iron, 12 grammes;
Citric acid, 4 grammes;
Distilled water, 24 grammes.—M.;

or—

℞ Citric acid,
Muriatic acid,
Perchloride of iron, } āā 4 grammes;
Distilled water, 32 grammes.—M.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, OCTOBER 9, 1880.

EDITORIAL.

WITH the present number the *Philadelphia Medical Times* begins its eleventh volume. It was originated by the Philadelphia medical profession, led by the feeling that there was no journal of its class which represented the medical thought and progress of a city which yields to none in America as a centre of professional activity. How far the hopes and desires which gave birth to the *Times* have met their fulfilment it is not for us to say; but we can point to the fact that at present nearly every Philadelphia medical society of importance publishes regularly through our columns. Surely this is no mean endorsement.

The supply of papers from the profession of the city has been steadily increasing, until during the last year it has become actually embarrassing and has threatened to crowd out material received from other parts of the country. Fortunately, at this juncture we are able to announce that, in the opinion of our publishers, the time has come for an increase in the size of the journal from an issue of twenty-four to one of thirty-two pages, *without increase of the subscription-price* (four dollars a year). By this means sufficient room will be obtained for all contributions; and, whilst the *Times* will continue to be the chosen exponent of the Philadelphia medical profession, it will also be able to draw, for the support of its columns and the benefit of its readers, from all portions of the United States.

DEATH FROM ETHER.—Mr. R. N. Hartley reports a case of sudden death during etherization by arrest of respiration. The patient was in a condition of great feebleness and suffering from obstruction of the bowels.

REVISION OF THE UNITED STATES PHARMACOPŒIA.

THE committee on the revision of the United States Pharmacopœia held, recently, a very important meeting at Saratoga. The tone of the discussions was, very properly, conservative, and it was decided to make no important alterations in nomenclature. Several new classes of preparations were adopted and one or two dropped. Of the former the more important were *Abstracts* and *Elixirs*. Abstracts, proposed by Professor Remington, of this city, are to be of the nature of extracts, but are dry powders so concentrated or mixed with inert material as to preserve a definite relation to the crude drug: we understand that they are to be twice the strength of the fluid extracts. This innovation seems to us a good one. There was a regular battle over elixirs, but finally their friends won the day by a vote of nine to eight. The closeness of the contest, we trust, will influence the number of the preparations. Elixirs are mostly frauds, not containing what they purport to do, manufacturing chemists having long ago discovered that the easiest and cheapest way of disguising strychnia, quinia, etc., is to allow them to penetrate only so far as the label of the bottle, or, at best, to be present in the syrup in very small amount. The wise physician who has a Xantippe of a wife takes an elixir, but for the use of the laity the prescription is of doubtful utility. We would have preferred such a name as Syrupus Aromaticus and Syrupus Curaçoa for the vehicles, which, it seems to us, should be the only medicines of the class introduced into the officinal list. The number of individual drugs and preparations which it was decided to elide from the present standard list was quite large: for obvious reasons we do not enumerate them here, especially as the decision is probably not final. It was decided that fluid measure should be employed for fluid extracts, and that the

formulæ should be such that one cubic centimetre of the preparation should represent one gramme of the crude drug. This differs theoretically five per cent. from the old strength of a minim to the grain; practically there is no difference between the two standards.

Dr. Squibb was at the meeting, and battled in vain against the elixirs. Possibly disgusted at this, and certainly overburdened by his private responsibilities, he positively enforced the resignation which he had from the first threatened, and Prof. Emil Scheffer, of Louisville, was elected in his place. Professor H. B. Prescott, of Ann Arbor, Michigan, was elected to the position vacated by the withdrawal of Professor Wormley.

It will be seen that the work on the revision goes along cheerily, with every prospect of being well done. It is yet too soon to be assured as to the time of completion, but we should think the book would be out early in 1882, or possibly by the close of next year.

CORRESPONDENCE.

LONDON LETTER.

THE nervous system is the main object of scientific medical attention at the present day. The experiments of Fritz and Hitzig, elaborated and worked out fully by Professor Ferrier, F.R.S., have drawn many other observers to work at the same subject, while the clinical observations of Dr. Hughlings Jackson have created quite a new school of clinical observers and teachers. Charcot's work also is of the highest value, as every one admits. There is coming out soon a work on the diseases of the nervous system, by Dr. James Ross, of Manchester, in which the evolution of the different portions of the brain and spinal cord is contrasted with the retrograde ravages of disease, which will excite the keenest interest. It will be illustrated by numerous magnificent engravings, which will add to its value. Though Dr. Ross has published little so far, he is known to be one of our best workers, and in the hurry and bustle of existence in the manufacturing area in which he resides disease of the nervous system of every variety and kind is rife, and affords him excellent opportunities for observation,—opportunities which he has not neglected, as will soon be apparent. Then, again, the study of the brain as "the organ of mind" is also now in the ascendant, and evolution is causing many old-established and generally-received views to undergo criticism and modification. Consequently it was with peculiar interest that I recently read a lecture, delivered by Dr. Hughlings Jackson some five years ago, on "Softening of the Brain." Up to a few years ago brain-decay, mental and motor, was promiscuously and indifferently spoken of as softening of the brain. Rokitansky described two forms,—"yellow" and "red" softening,—but few practitioners were influenced by what the great pathologist had to say, and a hazy impression prevailed that there was a general softening—such as the brain undergoes as a post-mortem phenomenon—going on in life in certain cases of brain-decay. Now, in the face of this impression, it may be well, and will be found instructive by many of your readers, to review what Dr. Jackson says in this lecture, which he lent me for perusal some few weeks ago.

He says we frequently hear the term "softening of the brain" used by educated patients who simply suffer slight and often but temporary nervous exhaustion, but who apprehend this organic change is coming upon them. It is also in use by medical men as a name for a certain rude clinical grouping of symptoms in cases in which there is really no softening. This group of symptoms he puts thus: "We see patients who have become excitable, irritable in temper, and desponding; they have found that their attention easily fails, and that they cannot do their accustomed work; they usually sleep badly; they have often what they call headache, but it is mostly not an ordinary headache, either in kind or position; it is a feeling of pressure, or sometimes of burning, and its seat is the vertex or the back of the head; there is very often, indeed, a disagreeable feeling at the occiput and in the upper parts of the spine more distressing than pain,—an intolerable physical feeling; the queer feeling in the spine is often intermittent, and frequently comes on slowly with great depression of spirits. Altogether, there is a strange mixture of 'mental' and 'physical' symptoms." This "group of symptoms" is described here by Dr. Jackson with a fidelity which every one of experience must recognize.

His explanation of these symptoms is that they "indicate nervous exhaustion, beginning often in the sympathetic nervous system, and secondarily affecting the nutrition of the highest centres in the brain. Of course this is only hypothetical, for there is no morbid anatomy of such cases." Excesses of various kinds, but still more misery or overwork, especially when the work is done under responsibility, are the chief exciting causes of this state. In the graver, more prolonged, and ingravescent cases he thinks there is not

softening of the brain, but rather greater firmness of it,—an atrophy of nerve-cells and fibres, with increase of connective tissue. He says, "Be sure there is no softening in these cases." And again (and this is an expression of opinion which ought to receive the greatest consideration from every thinking reader, as it certainly deserves it), "So far as I know, cerebral softening is always local. I know nothing of general or universal softening of the brain." Probably this announcement will seem strange to many, for it is made without qualification; and if Dr. Jackson does not know anything of general or universal softening of the brain, then no one else is likely to know anything about it. A certain amount of softening following encephalitis is found around tumors and other adventitious products, but this belongs to a distinct category. "The cases which deserve to be called cases of softening are cases in which there is blocking up of cerebral arteries, or—which is infinitely rarer—of cerebral veins. Of these only shall I speak," he goes on to say.

The portion of the brain most liable to softening is that supplied by the "middle cerebral" artery: hence hemiplegia and affections of speech are the symptoms most to be trusted in the diagnosis of cerebral softening. When perfect hemiplegia comes on in a quarter of an hour, without loss of consciousness, in a patient past middle age who has not renal disease, we are practically certain of local cerebral softening. There is in these cases softening by thrombosis,—a commoner cause of local softening than embolism. This is certainly not the group of symptoms ordinarily understood as pathognomonic of softening of the brain. The wide-spread impression that there *must* be general mental symptoms if there be "softening" is an error. Of course, "softening" such as is here described may have been preceded by evidence of brain-impairment in the group of symptoms given above, or may be followed by them, but in neither case do these symptoms directly depend on that softening. There is, however, one mental symptom in this local softening, and that is loss of speech. Deep coma may arise from blocking of the middle cerebral artery, as deep as that produced by large cerebral hemorrhage. Dr. Jackson says, significantly, "Affection of speech is a mental symptom. A person who has lost speech has lost a part of his mind." If the trunk of the middle cerebral artery be blocked, then there is very extensive softening, and a state very like imbecility, as well as loss of speech, follows; the patient's power of expression in all ways, and even the exhibition of states of feeling by smiling, may be gone. General mental symptoms may follow upon this typical case: "A patient about fifty has become hemiplegic without loss of consciousness. This is the symptomatic statement; the pathological statement is that he has local cerebral softening." In a little time the patient may begin to wander, although he can pull himself together and clear his mind of his fancies, and can reply to ordinary questions when required. He wanders about his business or other matters familiar to him, and so may mistake strangers around him for persons to whom he is accustomed. There is an automatic state of mind. As "evolution" is the development of the mind, so here there is "dissolution" or a reducing process, commencing in the higher centres first. Especially is this liable to happen when a low-diet treatment is adopted, and the arterial tension is insufficient to supply properly with blood the parts farthest from the heart. As such brain-mischief is very apt to happen to those who "every day for years have eaten and drunk far too much," such line of treatment is very apt to be selected. The arteries of the brain have long been growing degenerate, and the nutritive supply to the brain defective. The active mental symptoms are due to brain-starvation really.

It is quite clear that active mental symptoms cannot be set up in a part which has *lost* its functional power. There is then impaired power in the highest or controlling centres, and then the lower or automatic centres escape from their control. "In any general lowering of health the very highest nervous arrangements are the first to fail (principle of dissolution). The positive or active symptoms—the illusions, delusions, and grotesque actions—are owing to the action of the lower nervous arrangements, which, except for over-excitement *permitted* by the loss of control, are healthy (principle of loss of control). When a man is delirious—his negative state—I repeat that his highest nervous arrangements in the cerebrum, the substrata of consciousness, are more or less put out of use; he has defect of consciousness." Here Dr. Jackson puts a difficult matter with marvellous lucidity. We can see how delirium shows itself from debility or asthenia, whether in febrile or non-febrile disease, and how it should be more found in sleep, in dreaming, in less severe cases than those where it is present during the waking state. It is not the evidence of vascular turgescence of the highest centres, but of asthenia in them, associated with anæmia. "It is a grave error in any case to put these symptoms down to meningitis, encephalitis, or to any kind of primary head affection. It is a deplorable error if it leads to severe purgation, to blistering the back of the neck, leeches, and low diet. The characteristic symptoms of encephalitis, meningitis, and acute brain disease generally are not mental, but physical. Thus, besides gross motor affections, convulsion, and paralysis, there are alterations of circulation, respiration, temperature, and constipation, vomiting, etc. Do not forget this seeming paradoxical statement, that the trust-

worthy symptoms in the diagnosis of acute and primary disease of the organ of mind are physical, and that the untrustworthy symptoms for that diagnosis are mental." So much for the positive symptoms of "softening of the brain" as they actually occur in reality, and contrasting as they do with those signs of mental impairment which are generally supposed to indicate that lesion.

General mental symptoms may develop weeks or months after an attack of softening, but they follow at too long an interval to be attributed to the local damage done by the softening. A general mental and bodily failure often follows a severe attack of hemiplegia the result of local softening. It is not due to the softening, or to any extension of it; it is probably a result of secondary atrophy of the whole or of a large portion of the hemisphere in which the local softening lies. Such secondary atrophy may also follow clot or other large cerebral lesion. When mental deterioration does follow, it shows itself both intellectually and emotionally. There is loss of power in connected thought on difficult, novel, or complex subjects; that is, the patient is soon confused. Then there is moral degradation: the patient exhibits peevishness and selfishness,—childish characteristics. On "the principle of dissolution" the highest centres go first; those faculties last acquired by the race and by the individual are then the first to go. Then, patients with cerebral deterioration are easily excited, because the deterioration is most pronounced in the controlling processes. The more slowly these mental changes develop, the better; the more rapid, the worse the lookout. The inferiority of a brain as regards its moral qualities is readily demonstrated in disease: it is irritable, ready to take offence, shows bad temper and greediness. Better brains have a reserve of good feeling, and it takes a longer time for the work of dissolution to degrade them. This mental aspect of disease of the brain is very useful in clearing our impressions as to the minds of persons in health. Inferior brains reveal themselves in confusion and inability to see their way in anything new or complex; so disease soon lowers them.

To return to the pathological aspect of the subject. Excluding softening about tumors and other gross lesions, Dr. Jackson knows nothing of softening of the brain except that resulting from blocking of cerebral vessels; as to "extension of softening," he knows nothing of it except in the very simple sense of its resulting from new blockings up of arteries near those formerly blocked up. He lays stress on the fact that softening of the brain is an "arterial," not a "nervous," disease proper. Pathological changes commence in the arteries or in the connective tissues, not in the nerve-tissue proper. The nerve-tissue suffers, but is not primarily at fault. It is therefore hard to see how any mental changes which may have preceded softening could produce it; they may precede it, of course. He thinks, and a very painful recent experience gives weight to what he says, that overwork or anxiety may lead to that condition of brain—that is, excitability while there is wide-spread degeneration of the cerebral arteries, and thus a worse nutrition throughout the brain—before the actual softening of some part as the result of one of these rotten arteries being blocked up by thrombosis. Consequently modifications of the patient's ways may precede a local softening. It is often spoken of by the patient's friends as "alteration of the disposition;" irritability and selfishness are predominant. "This prior condition of ill nutrition does not lead to *general* softening, however slight we may suppose that softening to be," so far as he knows. He then goes on to review the general condition of patients whose cerebral arteries are liable to be blocked up. It is well to inquire into the state of the heart, arteries, and urine when a patient presents himself because he cannot use his arm or leg. "Suddenly-occurring and transitory slight symptoms, such as affections of speech, unilateral numbness, may be owing to little foci of softening (or, rather, to thrombosis of small arteries, which in due time lead to softening), just as much as permanent paralysis may be due to extensive softening. Of course, the slighter the symptoms, the more need is there practically to consider many possibilities, for slight symptoms are not necessarily so easy of explanation as grave symptoms often are. Slight and transitory hemiplegia—which we are warranted in putting down to blocking up of very small arteries—is often hastily ascribed to general states of ill health,—for example, to affection of the liver, etc. At the same time, it is only an inference that such slight and transitory paralytic symptoms depend on small foci of softening, for there is no, or practically no, morbid anatomy of such slight symptoms."

Now, in this lecture Dr. Hughlings Jackson has told us, with much perspicuity, what is the pathology and what are the clinical phenomena of softening of the brain; he has not only taught us much positively, but also much negatively. He has told us that the group of phenomena, physical and mental (especially the latter), which have been in the past regarded as pathognomonic of softening of the brain, are not associated with any such lesion. He has told us, in decisive language, that he does not know any general symptoms of brain-softening, and that when that morbid change does occur the phenomena manifested are motorial, not mental. So far, so good. But will some authority on diseases of the nervous system kindly tell us what is known, or even believed, about the pathological condition underlying that group of symptoms given with such fidelity by Dr. Jackson, and quoted

in the early part of this letter, which our forefathers, our immediate predecessors, and even the bulk of the present generation, call "softening of the brain"?

J. Milner Fothergill.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held at the hall of the College of Physicians, Philadelphia, September 8, 1880, Dr. Albert H. Smith, President of the Society, in the chair. Dr. W. R. D. Blackwood read a paper on the "Treatment of Dysmenorrhœa by Electricity" (see p. 3), which was received with marked attention. He illustrated the lecture with large diagrams, and exhibited a number of special electrodes of his own design for use in uterine electro-therapeutics, with others adapted to general purposes.

DISCUSSION ON THE ELECTRICAL TREATMENT OF DYSMENORRHŒA.

Dr. Charles K. Mills said that he had found the faradic current very serviceable in young girls where the menses were slow in appearing, and where nervous symptoms and pain were present: in such cases the rheophores, well moistened, were applied externally over the sacrum and above the pubes. In dysmenorrhœa electricity is also very useful, but will not succeed in all cases.

Dr. W. R. D. Blackwood, in reply to a question, said that he had used electricity in cases of menorrhagia, although not very often, as the effect, though marked, is temporary. Faradism produces, undoubtedly, instantaneous contraction of the uterus, and in post-partum hemorrhage is very effective. For this purpose a battery made by Drescher, of New York (an improvement upon the small Gaiffé instrument) is well adapted, and can be carried in the pocket or the satchel. Where bleeding threatens to become extensive, he constantly resorts to this expedient, and always finds it to produce rapid and complete contraction of the uterus, which, moreover, remains contracted.

The speaker had never seen the hemorrhage made more profuse by electricity. In cases of dysmenorrhœa the flow is decidedly increased in quantity, especially at the first period after its application; it is less so at subsequent periods, but even at first is not excessive or sufficient to cause any alarm. When amenorrhœa follows a prolonged sea-voyage the application of electricity produces very marked effects, the flow coming on very soon after the proper use of the battery, the electrical sound being preferably employed in the uterus. By the use of the same instrument with a strong galvanic current through zinc rheophores he had been able to produce a caustic effect upon the mucous membrane: indeed, in one case of membranous dysmenorrhœa he had heated the galvano-caustic porcelain-tipped sound, and, passing it along the entire uterine canal, produced the effect of the actual cautery. The case was at once relieved, and subsequently entirely recovered.

Dr. Henry Leffmann, referring to the diagram, observed that it appeared as if, with the double pole instrument, there must be a loss of electricity, according to the axiom that where there are two parallel currents of electricity there is a loss in the strength of the current.

Dr. J. L. Ludlow agreed with the lecturer concerning the want of appreciation of electricity among the profession generally. With reference to the subject under consideration, he believed that neuralgic cases of dysmenorrhœa would be more likely to be benefited by electricity than any other variety, as they also are less amenable to treatment by ordinary methods. He mentioned two cases where a change of locality was followed by entire relief from dysmenorrhœa, which, however, reappeared when the patients returned to the city. He could only attribute the relief in the first instance to the change of residence and the electrical condition of the atmosphere.

The President said that he would like to ask the lecturer to explain, in the application of the galvano-cautery in the case of membranous dysmenorrhœa to the entire internal surface of the uterus, whether he wished to be understood as saying that he resorted to the caustic application of high heat, or the stimulating effect of a lower degree of temperature.

In regard to the use of electricity in the treatment of uterine troubles the President acknowledged that his views had been materially modified within a few years, and he now feels less enthusiastic on the subject than he did earlier in his practice. He had generally found immediate relief from the pain and other symptoms; so that very high hopes were entertained by the patients of permanent relief. They were delighted with the trial, but he had very seldom seen their expectations realized, and in some cases the depression of spirits caused by the disappointment did the patients more harm than the electricity had done them good. He had never used the double electrode described by the lecturer, having only employed the stem or a small metallic globe in contact with the uterus, the other electrode being a large sponge placed externally over the hypogastrium or in the sacral region; by varying the position of the external pole the objection of one of the former speakers could be obviated.

There is no danger of increasing hemorrhage. He had never known it to produce any trouble, nor is there any contra-indication to its use. He had always looked upon elec-

tricity in this application as chiefly a local anæsthetic, and had found it to give much relief to cases of dysmenorrhœa. In many cases, however, the pain begins after the flow has begun, which makes the application practically unavailable.

In reply to a question, the President said that the anæsthetic effect, or the relief from the pains of dysmenorrhœa, was very decided after the first application; the second time, the effect was much diminished, and it gradually diminished until finally there was no effect whatever. This had been his own experience; but he was glad to hear that the lecturer had been more successful.

Dr. Blackwood, in closing the debate, said that he had never had a case in which the results had proved that electricity had done any harm. He would not say that electricity is the sole remedy, or that it is to be used in every case; but under proper conditions it will be successful after the failure of all other treatment. In hundreds of cases he had used it without any evidence of injury and with *permanent* success. Many such instances are of ten years' standing. It hastened the appearance of the menses at times, and usually increased the quantity of the flow at first, but not to excess. He had seen cases, just like those mentioned by the President, in which immediate benefit was not attained in the early applications, but he had found that ultimately these cases do well if the treatment is persevered with. Treatment should not be discontinued after a few trials, but it must be persistently applied for eight or ten months, or longer, until decided relief is obtained. Of course some exceptions may exist to this rule. As to the time of application, he had very rarely used electricity after the flow had become established unless pain is then present, when, if the suffering is severe, the battery is employed. Galvanism and induction currents have the power to relieve the pain of dysmenorrhœa, just as they alleviate any other pain. He had found electricity capable of relieving the muscular pains of remittent and intermittent fever, either by general galvanization, according to the plan of Beard and Rockwell, or by applications through the solar plexus.

The objection of Dr. Leffmann does not hold good against the plan proposed of doubling one of the poles, the other being in the uterus. There is no loss of current and there are no parallel currents as thus applied, and the entire current must pass out through the uterine tissues by way of the intra-uterine sound, which is insulated to the point where it enters the uterine canal.

In conclusion, he said that he was satisfied that by persistence in the treatment, with proper apparatus, and especially by using the galvanic current, electricity can relieve, and that permanently, ninety per cent. of cases of dysmenorrhœa. Those most likely to be relieved are the neuralgic patients; the next most frequently treated with success are congestive cases. In the latter the uterus can be brought to its healthy condition without the use of any constitutional remedies or caustics. In a case of endometritis with excessive congestion, recently under his charge at St. Mary's Hospital, the uterus had been much reduced within two weeks.

In replying to the question as to the application of the actual cautery, he said that he had used the porcelain button at a low heat, which he had passed throughout the length of the uterine canal. The case had been thoroughly cauterized previously by the usual remedies, but without effect. She had no more casts after the use of the electricity, and has now reached the menopause in perfect health.

In some cases the speaker uses other remedies besides electricity in the treatment of uterine troubles. Ergot and viburnum prunifolium had given him good results. He had brought the paper before the Society for the purpose of insisting that by persisting in the proper, systematic, and thorough application of electricity we can cure the majority of cases of dysmenorrhœa and greatly relieve the rest.

On motion, a vote of thanks was given the lecturer for his interesting paper.

RENAL CALCULUS.

Dr. William T. Taylor reported the following case. On the 30th of August, 1880, he was, early in the morning, called to see a patient suffering with intense pain in the lumbar region on the left side, which, though relieved by anodynes, returned several times during the next few days. The pains radiated from the left side and went to all portions of the body. On the fourth day the pain seemed to be located in the bladder, which was quite irritable. The patient was ordered diluents and diuretics, and on the morning that the report was made he passed a small stone from the urethra, which was presented, and, on motion, referred to the Committee on Microscopy for examination.

HEMORRHAGE CAUSED BY ACID NITRATE OF MERCURY.

Dr. Charles B. Nancrede said that he had two interesting cases to report. The first one illustrated the disadvantage of the practice of some practitioners of at once applying the acid nitrate of mercury to all sores upon the penis. He had been called in consultation to see a case of alarming hemorrhage from the dorsal vessels of the penis, following the above treatment. He was obliged to secure both dorsal arteries by acupressure. He subsequently had some return of the hemorrhage, but it was readily checked. Sloughing also followed, which opened the urethra, and required a plastic operation. The patient subsequently recovered, and has had a healthy

child, so that in all probability the first lesion was not syphilitic.

A CASE OF SUBLUXATION OF THE SCAPHOID BONE.

The second case is that of a man who fell from his wagon and struck his hand. It was thought to be merely a sprained hand by the resident physician, but when examined a few days later it was found that there was a subluxation of the scaphoid, much to his surprise. By making a strong pressure upon the prominent bone anteriorly, and suddenly flexing the wrist, the bone was restored to its place; a plastic dressing was applied, and the patient soon after was discharged. This accident is quite rare, and is mentioned only by Chisolm, of Baltimore. The scaphoid was not entirely out of its place, but was firmly jammed in a new position, so that its edge presented to the radius.

Dr. William M. Welch also related a case of severe hemorrhage from the penis following the application of acid nitrate to a simple sore by a homœopathic practitioner.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, SEPTEMBER 9, 1880.

THE PRESIDENT, Dr. S. W. GROSS, in the chair.

Ulcerated scirrhous carcinoma of the mammary gland occurring at an early age. Presented by Dr. SAMUEL W. GROSS.

THE specimen before you is the entire left breast, which I amputated this morning. The patient, a married, prolific female, 27 years of age, first noticed, twenty months ago, a nodule to the outer side of the nipple, which gradually increased until the entire gland was involved. The glands of the axilla were observed to be enlarged in eight months, the nipple began to retract in twelve months, and the skin was superficially ulcerated in seventeen months, from the commencement of the disease. During the last four weeks the axillary glands increased to three times their former size, became densely indurated, and fixed to the axillary border of the great pectoral muscle and the side of the chest; the superficial ulceration was converted into a deep, crater-like sore; several nodules appeared in the skin at the inner circumference of the growth; and the mass attached itself to the pectoral muscle. There was no history of heredity, trauma, or psoriasis or eczema of the nipple.

The operation was made as thorough as possible by removing the entire gland along with its skin and subcutaneous fat, the greater portion of the pectoralis major muscle, and the involved lymphatic glands.

The interest of the case consists mainly in the comparatively early age at which the disease was first observed,—namely, twenty-five years and four months. In my "Practical Treatise on Tumors of the Mammary Glands," which has just appeared from the press, I state that out of one hundred cases of carcinoma of the breast of which I had a record the earliest age that I had observed was twenty-eight years. Since the chapter on carcinoma was written I have met with twenty-six additional instances, and the one now recorded was the only one noted before the age of thirty.

Foreign bodies in the external auditory canal. Presented by Dr. CHARLES H. BURNETT.

The young roach which I show you I removed alive from the ear of an Irish chambermaid in one of our large hotels last Tuesday morning. The patient stated that the evening previous, about nine o'clock, as she lay down upon her pillow, she felt something run into her ear; that she immediately experienced great and peculiar discomfort rather than pain, and that the intolerable annoyance of the movements of the creature and their attendant noises had continued all night, entirely banishing sleep. She looked very anxious and distressed, and had she not been of very large and muscular frame and in apparently robust health might have manifested graver nervous phenomena. I have known the entrance of a common fly into the ear of an infant to cause convulsions.

Under good illumination of the auditory canal by means of the forehead-mirror, I saw the central portion of the roach well down the canal, extending from above downward. This part I seized by means of delicate forceps with slender blades, and extracted the invader alive. It was 1 cm. long and 4 mm. wide at the widest part, not counting the antennæ, which are fully as long as it is. Instantly all the patient's discomfort ceased, and on examination it was seen that no harm had been done the ear at any point.

A great mistake is often made in such cases, first in supposing that the insect can do great harm, and secondly in making various rough and injurious endeavors at extraction.

The injury that does often arise in such cases is purely *post hoc*, and not *propter hoc*, as the aural surgeon sometimes has an opportunity of seeing.

Not long since, a distinguished aurist of Boston was called to see an old lady in one of the prominent families of that city, in order, as it was told him, to remove something from her ear. As he was hastily summoned, he went at once, and found the old lady in great distress and just getting over the effects of ether. The statement made to him was that her little grandchild, while playing with her on her lap, had put a small shirt-button into its grandmother's ear, and that, though it produced no discomfort, it was deemed best to summon their family medical adviser, who was

a homœopathic physician, and have it taken out. This was done, and the so-called physician examined the ear and said he could see the "button distinctly, as it was quite pearl-like in appearance." He then proceeded to extract the foreign body, but failed to do so, and, besides, gave great pain to the patient.

Finally, ether was resorted to, and a prolonged gouging and probing carried on, but no button could be got from the ear. For various reasons, the man ceased his manipulations and retired; the old lady recovered from her narcosis, but showed great signs of prostration; and, as it was supposed that the button was still in the ear, the aurist alluded to was summoned to extract it and relieve the suffering erroneously supposed to be due to its presence. He found that there was no button in the ear, and there was reason to believe there never had been, as the button which had been said to be in the ear was found subsequently on the floor near where the child and its grandparent had been sitting. What the first physician called in had seen and supposed was the button was the membrana tympani, which in the normal state looks like a pearl in color. To this he had directed his efforts, and *gouged it and the ossicles of hearing entirely out*, thus, of course, destroying the ear forever.

In my experience, a man, a junior partner in a machine-shop, called on me for relief from discomfort in his ear and deafness. He was a large, strong man, but was pale, anxious, and bathed in clammy sweats, manifesting, in fact, symptoms of shock. He stated that a few days previous, while crossing a street in front of a horse, the latter had splashed mud into his ear. No discomfort, save a little dulness of hearing, ensued; but on stating the occurrence to his comrades in the shop they insisted on his having the mud taken out, and they proposed to extract it, which they proceeded to do with wires and small tools. This caused great pain, but it was misconstrued as a sign of need of all the more sedulous endeavors at extracting the mud. Manipulation of the roughest kind was continued on the ear, until the man could endure it no longer. Great and continued pain ensued; the hearing remained dull,—in fact, became worse, and the man had to desist from work. Some little mud was taken out by his companions, and "several small white pebbles," as he said (most probably the ossicles). But as the pain and deafness continued, with some symptoms of dizziness and tension in the head, he concluded to seek medical advice.

Examination revealed *total destruction of the membrana tympani, it having been clearly cut away from its attachment to its bony ring, and all ordinarily visible parts of the ossicles had been similarly removed by his rough companions.* A few jets of warm water from a syringe would have removed all the mud had it been used at the first.

It is plain to be seen that two very important considerations arise at the outset when a foreign body is or is supposed to be in the ear. First, make sure of the diagnosis; and, secondly, make no effort at extraction which will do more harm than leaving the foreign body there, whether it be animate or inanimate. Presence of mind, too, on the part of the would-be surgeon as well as in the patient will always prove to be of the greatest aid.

This summer, a gentleman, just after he had gone to bed, felt an insect enter his left ear. He, of course, felt all the usual and peculiar annoyance from its movements. Being entirely alone in his house, he was thrown altogether on his own resources at the outset. He bethought himself in his extremity of a novel method of inducing the insect to come out, for he struck a light and held his ear as close as possible to it. He says he felt the insect turn and retrace its steps and come to the mouth of the ear, when he seized it with his finger-nail, which act caught and tore off its head. Death ensued, and all movements ceased in the insect, the body of which the patient removed at his leisure.

It would be well for doctors as well as patients to know that not the foreign substance so much as the unskilful and *rough treatment often practised is the real cause of the damage* which sometimes occurs *after* a foreign body has been in the ear. The most efficient treatment is to drop a little warm water or oil into the affected ear, and employ the syringe. Instruments should be used only by the expert.

PHILADELPHIA ACADEMY OF SURGERY.

MEETING OF MAY 3, 1880.

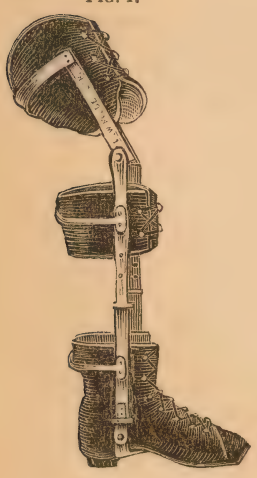
DR. S. D. GROSS, President, in the Chair.

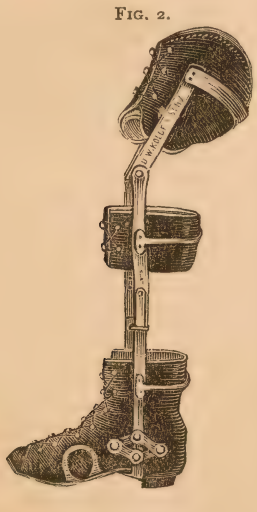
ON THE TREATMENT OF CLUB-FOOT.

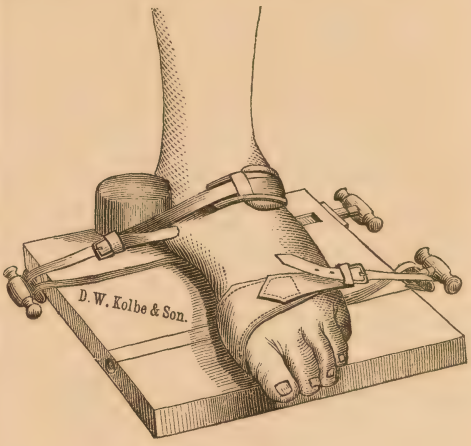
SEVEN cases of congenital varus and equino-varus, which had been under treatment for varying periods of time, were presented by Dr. Thomas G. Morton to illustrate the manner of dealing with these deformities in the Orthopædic Hospital and in his private practice. In all cases the treatment, Dr. Morton believed, should commence in earliest infancy, with the view, at first, of correcting the varus, and consists in frequent daily manipulations of the foot and carefully-directed pressure on the tarsus by the hand of the mother or nurse. No apparatus is available at this tender age, and no tendon should ever be divided for the relief of club-foot in infancy, for a varus can, by careful and persistent stretching of the foot, always be overcome; only now and then the plantar fasciæ must be divided. It is difficult and often impossible to reduce an equinus, but this deformity can also by stretching be much improved,

and can be corrected by operation much better when the child is able to walk. Indeed, it is better to delay the section of the tendo Achillis until the child is two or three years of age, as the elevation of the heel during this time gives rise to but little inconvenience. If this tendon is cut early, a rigid contraction generally results. After the varus is corrected and the child is ready to walk, a brace is necessary to overcome the tendency to a recurrence of the deformity. The ordinary club-foot walking-shoe allows only of a hinge-motion, and, as a frequent stretching of the ankle-bones outward is desirable, Dr. Morton has long employed for this purpose a modification of the usual apparatus, as follows. Taking an ordinary leather shoe, which should lace up in front, with the lateral steel supports running up above the middle of the thigh, with transverse braces and bands above and below the knee to hold the apparatus in position, he has had an additional hinge placed (Fig. 1) opposite the external malleolus, and opposite this point a portion of the inner steel rod has been taken out, and replaced by a double antero-posterior hinge or toggle-joint (Fig. 2), which enables it to yield when pressure is made upon it, while the hinge in the

FIG. 1.







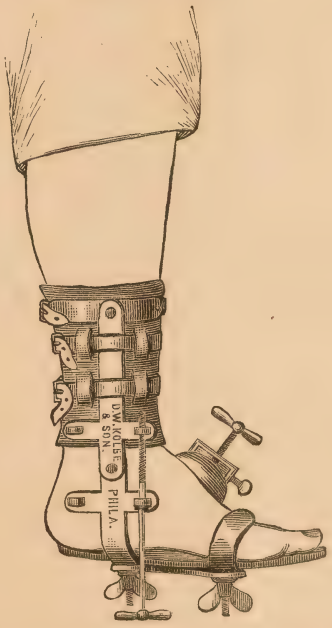


FIG. 2.

outer support allows the turning out of the foot each time it is brought down to the ground. The weight of the body resting upon it with each step gives, by this means, an outward movement or partial rotation of the foot, which is consequently communicated to the tarsus, so that this portion of the articulation is made more pliable.

In children where operations have, either through neglect or ignorance, resulted in stiff and unyielding deformity, and in adults never subjected to treatment, it becomes necessary after the division of tendons and fascia to stretch the foot at once into position by powerful pressure. For this purpose Dr. Morton has invented an apparatus which he has used in conjunction with manipulation, consisting of bands and screws, which can be applied first under anæsthesia, in order to force the condensed and rigid tarsus and surrounding tissues into a normal position. Other forms

of apparatus for a similar purpose he has employed with the same object in view, and with their aid he has been able to accomplish very much. He has never seen a case where excision of the tarsal bones was required. It is quite probable that in some rigid adult cases the tarsal bones have been fractured, however, by the power employed with the stretcher.

Some of the cases presented as illustrations were cured, others remarkably improved, by the methods described; and Dr. Morton, in

concluding, stated that after stretching or tenotomy he always uses for some days a posterior well-padded tin splint, and has the foot dressed morning and evening, carefully avoiding any irritation of the skin, and that the only forms of talipes which gave trouble were equino-varus and varus, hence he had confined his remarks to these varieties of club-foot.

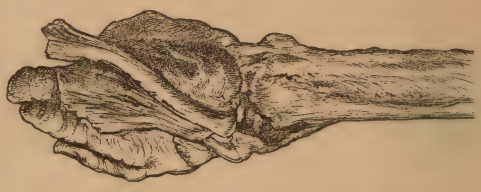
Dr. S. W. Gross considered it improper to endeavor to cure the varus and the equinus at the same time, but thought it better to treat the varus first and then the equinus. Stretching is really subcutaneous rupture, and is therefore of value. He is accustomed to stretch the parts by bending them over his knee, and uses plaster-of-Paris dressings to maintain eversion of the foot. If bony anchylosis of the tarsal bones occurs, excision of a wedge of bone is necessary.

Dr. Packard exhibited a foot removed by him from a child who had had congenital varus in both feet. Spontaneous separation of the left foot had taken place, apparently from pressure on the soft parts in walking, the only connection between the leg and foot being a strip of skin on the inner side.

A full report of this case will be elsewhere given.

CASE OF PRIMARY EXCISION OF THE ELBOW.

Dr. John H. Packard presented a patient upon whom, some years ago, he had performed a primary excision of the elbow-joint for compound fracture. The excision included portions of the humerus, radius, and ulna. The man has excellent motion, with good control of the arm, and is able to follow his occupation. Since the operation, some necrosed bone has been discharged from the neighborhood of the injury.



SPECIMEN OF FRACTURE OF THE LOWER END OF THE RADIUS.

Dr. William Hunt had recently amputated an arm for compound laceration of the elbow, complicated with rupture of the brachial artery, due to a fall, and was therefore enabled to obtain this valuable specimen of fracture of the lower end of the radius, produced by the same accident that had necessitated amputation for the severe lesions about the elbow.

The deformity at the wrist was the typical one known to all surgeons, and was represented to the Fellows by a wax model made before dissection of the specimen. The injury was simple, but when the soft parts were laid open considerable comminution was evident. The principal line of fracture seemed to be oblique, and there was a breaking off of the styloid process and of the posterior edge of the bone.

Dr. Hunt called attention to the satisfactory and simple explanation that the specimen gave of the projection of the lower end of the ulna, which has been the subject of so much discussion. This is annoying to both patient and surgeon, and often impossible to remedy completely. The fact is, that nothing whatever is the matter with the ulna or its radial connections, but the carpus loses the support of the malleolar-like projection of the external border of the radius by reason of the fracture. Hence it and the entire hand are drawn by muscles or fall to the radial side. In other words, the ulna is stationary and everything below it is pulled away from it. There is a close analogy to what so often takes place in Pott's fracture of the fibula, where, the external malleolus, or the shaft just above it, being broken, the foot follows the fragment, and leaves a great deformity in the projecting tibia, although this is really in its place and is not necessarily the seat of any lesion.

This view of the projecting ulna also explains the remarkably good use of the wrist and hand which is often acquired, notwithstanding very great deformity. All that participates in the joint-structure proper is together in mass, for the ulna is not part of it: therefore, if the repair is good, good action follows, although more or less deformity exists.

Dr. R. J. Levis believed it well to drop the names Colles's and Barton's fracture, as they tend to confuse the subject. Colles's description of the form of fracture was erroneous, because he placed the line of separation too high. The fracture described by Barton—namely, a small piece chipped off the dorsal edge of the radius, with slipping up of the carpus—never exists except as an accompaniment of comminution. The fracture is produced by cross-breaking strain, and is, as a rule, transverse. There may be impaction when the lower fragment is driven above the upper, so that the former is split.

Dr. O. H. Allis had dissected a fracture of the radius after death had occurred from injury to the pelvis, and found it to correspond with the description of Dr. Levis. It was a transverse fracture with splitting of the lower fragment.

Dr. John H. Packard had found in many dried specimens no chipping of the posterior lip of the bone. Barton had also described a breaking off of the anterior lip or edge of the lower extremity of the radius, which he stated had different symptoms from the fracture of the posterior edge. Dr. Packard believed the deformity usually seen in fracture of the lower end of the bone could not be

produced by the injury described by Barton. It may be obtained, however, by bending the hand of the cadaver backwards. The deformity remaining after treatment depends on want of proper reduction of the fragments at the time of the injury. It may be reproduced, after reduction, by muscular action. The specimens and history presented by Dr. Hunt were remarkable, since the occurrence of the wrist- and elbow-injuries must have been simultaneous.

COMPOUND SEPARATION OF THE LOWER TIBIAL EPIPHYSIS.

Dr. John H. Brinton exhibited to the Academy a model of a separation of the epiphysis at the ankle, which was compound in its character. The boy, aged about 10 years, was treated conservatively for ten days, when amputation was required. The case was mentioned as bearing on the subject discussed at the last meeting of the Academy.

Dr. O. H. Allis had seen a similar case die of tetanus.

FRACTURE OF PATELLA.

Dr. R. J. Levis presented a patient who had recently been treated for fractured patella by the modified Malgaigne's hooks devised by himself. There seemed to be bony union, and little or no difference in the length of the two patellæ could be noticed.

JOHN B. ROBERTS,
Recorder.

REVIEWS AND BOOK NOTICES.

A TREATISE ON THE PRACTICE OF MEDICINE. By ROBERTS BARTHOLOW, M.D. New York, D. Appleton & Co., 1880.

We confess to a feeling of disappointment after examination of this work: we find it simply a well-thought-out and well-written volume, offering, so far as we can make out, no remarkable attractions to the practitioner who already possesses the received students' books. We had expected a larger and more pretentious treatise, whose sixteen hundred or two thousand pages would really exhaust the subject of the practice of medicine. In our early days, Wood's and Watson's Practices, clad in finest leather and majestic in the dignity of two portly volumes, graced every student's table. Now, forsooth, after twenty years of rapid and continuous growth, the science has to content itself with one more or less diminutive muslin-enclosed volume. There is not to-day any good American or English practice of medicine that we know of which unites the freshness of a thoroughly new book with the elaborateness of such classics as we have just mentioned. Surgeries and systems of surgeries abound. What, then, is the matter with the professors of medicine? Possibly the explanation is to be sought in the tendency of human nature to follow a lead. Prof. Flint attained great success because he perceived that there was a demand for one-volume works on practice; this success led to an inundation with books of the class. The next great similar achievement, we opine, will be made by some one who perceives that there is need for works between the one-volume practice of medicine and the excessively elaborate and expensive monographs that require a bookcase for a set. Prof. Bartholow's work will, we have no doubt, sell well, as it deserves to, since it is one of the best books of its class; but it is a text-book, not a great classical treatise upon the practice of medicine.

ATLAS OF SKIN DISEASES. By LOUIS A. DUHRING, M.D., Professor of Skin Diseases in the Hospital of the University of Pennsylvania, etc. Part VII.: *Eczema* (pustulosum), *Impetigo contagiosa*, *Syphiloderma* (papulosum), *Lupus vulgaris*. Philadelphia, J. B. Lippincott & Co., 1880.

In attempting the delineation of eczema pustulosum, Dr. Duhring has grappled with one of the most difficult subjects likely to engage his attention, and to say that he has succeeded in portraying this disease is too faint praise. He has not only made a good picture, but he has done well where all his predecessors have failed. A comparison of this plate with those of Wilson, Tilbury Fox, or even Hebra, shows an almost universal failure in former attempts, and a more than excellent result in this. It is, in fact, impossible to say too much in laudation of this American atlas, for each new fasciculus is a fresh triumph over innumerable difficulties,—a victory of mind over matter.

Although the remaining plates in this fasciculus have not, we suppose, given the author so much toil and anxiety for their perfecting as the one just mentioned, yet they are all equally successful. The picture of impetigo contagiosa is the first successful delineation of this disease which has ever appeared, and its careful study is commended to the general practitioner, since the affection is almost entirely unknown to the profession at large, though it is at times exceedingly prevalent, and its contagious character is liable to cause it to be confounded with syphilitic and other disorders. The portrait of syphiloderma papulosum is simply perfect; as a representation of the affection, the resources of the chromo-lithographic art could hardly go farther. The final picture of this fasciculus represents a fair average case of lupus vulgaris, and should be carefully studied in connection with the plate of lupus erythematosus in the first fasciculus; the differences between the two affections are very well brought out.

As to the letter-press, being Dr. Duhring's,

it is unnecessary to say that it is brief, clear, concise, and authoritative.

PHOTOGRAPHIC ILLUSTRATIONS OF SKIN DISEASES. By GEORGE HENRY FOX, A.M., M.D., etc. Parts XI. and XII. New York, E. B. Treat.

Part XI. of Dr. Fox's atlas contains plates representing *Herpes facialis*, *Hydroa bullosum*, *Erythema circinatum* and *E. exfoliativum*, and *Purpura simplex*. The picture of herpes facialis is a good representation of a severe form of the eruption ordinarily known as "fever-blister." The case is a very unusual one, and worthy of special examination on that account. The picture of hydroa also represents a rare form of skin disease, and one not yet recognized by all dermatologists. Dr. Fox gives his reasons for giving this affection a distinct place in dermatological nosology, and describes its chief distinguishing features with considerable detail. The plates of erythema represent also unusual forms of skin disease. That of E. circinatum is very good, while the picture of E. exfoliativum does not convey, to our mind, any notion of what appearances are intended to be represented. The plate of purpura is a fair picture of this affection.

Part XII. (concluding the work) contains plates of *Cornua cutanea*, *Alopecia areata*, *Morphœa*, *Scleroderma*, and *Sarcoma pigmentosum*. Of these, the cutaneous horn, though striking, is not a good picture; its chief interest is in the evident connection shown between cornu cutaneum and epithelioma. The picture of alopecia areata gives a fair idea of this affection, but is not a fine picture: it reminds us of the Cheshire cat in "Alice in Wonderland," gradually withdrawing from view in a sort of mist. The picture of morphœa gives some notion of the lesion, but that of scleroderma is less good, and would hardly, we think, convey a distinct idea of the disease to a beginner. The plates representing sarcoma are very striking, and fitly terminate a work which, while it can make no pretension to vie with the lithographic pictures of skin diseases presented in this country and abroad, nevertheless must take a place in the collections of dermatologists, and which, including especially the admirable descriptions of disease given by the author, is a work highly honorable to the profession of this country.

DISEASES OF THE THROAT AND NOSE, INCLUDING THE PHARYNX, LARYNX, TRACHEA, ŒSOPHAGUS, NASAL CAVITIES, AND NECK. By MORELL MACKENZIE, M.D. 8vo. Vol. I.: DISEASES OF THE PHARYNX, LARYNX, AND TRACHEA. Philadelphia, Presley Blakiston, 1880.

The first volume of Dr. Mackenzie's long-promised work is at hand. Should the second volume sustain the high character of labor so evident in the first, the completed work will take a high position in the branch of medicine of which it treats. It is both practical and learned; it is abundantly and well illustrated; its descriptions of disease are graphic; and the diagnoses the best we have anywhere seen. To give examples of the thoroughness of Dr. Mackenzie's book, we may cite the chapter on diphtheria, which embraces forty-seven pages. The chapter on non-malignant tumors of the larynx would appear to be absolutely exhaustive. Nowhere else have we seen so elaborate a statement of the subject. A very suggestive chapter is given on the anginæ caused by poisonous drugs, which includes the peculiar appearances due to certain constitutional impressions following the administration of mercury, antimony, iodide of potassium, arsenic, and belladonna. A very valuable appendix embraces a number of formulæ for topical remedies.

We must accuse our author of being occasionally a trifle pedantic, as when he speaks of painful deglutition as odynophagia, and displays over valuable space of his pages the synonyms of the various affections embraced in his text. It is a matter few persons feel a very vivid interest in that "tonsille ipertrofiche" is the Italian for enlarged tonsils. The select students who may be eager to possess this knowledge will most likely, long before the printing of this work, have secured a polyglot dictionary.

We can predict for this work a high position, and congratulate its distinguished author upon its appearance.

GLEANINGS FROM EXCHANGES.

UTERINE HÆMOSTATICS.—At a recent meeting of the British Medical Association (*Brit. Med. Jour.*, vol. ii., 1880, p. 367), Dr. Lombe Atthill read a paper on this subject, confining his remarks to the means of arresting hemorrhages from the unimpregnated uterus. The commonest causes of these were: 1. The various forms of cancer. 2. Tumors of the uterus. 3. Imperfect involution of the uterus after labor or abortion. 4. A granular condition of the intra-uterine surface. 5. Retention of a portion of the ovum after abortion. As to cancer, Dr. Atthill's opinion of the Chian turpentine treatment was favorable, although not to the extent of Mr. Clay's views as to its curative powers in malignant disease of the uterus. It seemed to exercise its greatest power in cases of epithelioma of the cervix, and to have comparatively little influence in the medullary form of the disease. The value of turpentine in cancer of the uterus seemed to be mainly due to its action in diminishing the blood-supply. The small supply of Chian turpentine and the difficulty of obtaining it pure were serious objections to

its use. Dr. Atthill believed that a pure oil of turpentine, administered in from ten- to twenty-drop doses three or four times a day, was, as a hæmostatic, quite as good, and that, if carefully rubbed up with powdered gum arabic or tragacanth, it was likely to agree with most patients.

To restrain the hemorrhage from fibrous tumors, the injection into the uterus of the liquor ferri perchloridi and of the tincture of iron had been advocated. This method was sometimes followed by satisfactory results; but it was not absolutely safe, and unless care was taken to provide a free exit for the fluid injected, either by previously dilating the cervix uteri or by using a double canula, serious results might follow. The injection of hot water in such cases was a far safer method of restraining the hemorrhage. Incising the cervix was often useful in being followed by a diminution in the hemorrhage and by relief from pain, and at the same time it permitted the introduction into the uterus of a tube of moderate size and the free return of the hot water, which should be injected at a temperature of about 110° F. Another simple and often effectual method of applying heat was the use of Chapman's spinal hot-water bags. Of drugs, none could equal ergot in its power of restraining the hemorrhage depending on fibrous tumors. It was most effective when administered hypodermically.

Imperfect evolution of the uterus implied primarily a relaxed state of the muscular tissue of the organ and an unduly distended condition of the uterine vessels, and also, in most cases, an unhealthy condition of the intra-uterine mucous membrane. When the latter existed it must be cured by treatment directed to the intra-uterine surface. To check the hemorrhage at the time of its occurrence hot water was a safe plan of treatment, and, generally, easily carried out. Ergot, quinine, and strychnine were, in cases of imperfect involution of the uterus, indirect hæmostatics. In the chronic form of the affection, Dr. Atthill had administered Chian turpentine with benefit.

Hemorrhage due to a granular condition of the vaginal aspect of the cervix might be arrested by the direct application to the bleeding surface of almost any astringent; but to prevent its recurrence a healthy condition of the cervix must be brought about by the free application of some strong caustic.

The retention of a portion of the ovum after abortion sometimes gave rise to very troublesome hemorrhage. In such cases dilatation of the uterus and removal of the retained portion by a curette might be performed unless contra-indicated, but it was liable to give rise to cellulitis and even to peritonitis, and Dr. Atthill therefore strongly recommended in such cases, at least as a preliminary measure, the syringing out of the uterus with hot water. He had no faith in the administration of astringents by the mouth in cases of uterine hemorrhage depending on the causes which he had enumerated. In conclusion, he suggested that the most important questions for discussion in connection with the subject of uterine hæmostatics were these: 1. What is the value of Chian turpentine in arresting hemorrhage in cases of cancer of the uterus? 2. Is Chian turpentine the only variety of the drug of use in such cases? 3. In what other forms of uterine hemorrhage is the administration of turpentine indicated? 4. What is the value of the intra-uterine injection of hot water: (*a*) in cases of hemorrhage depending on the existence of fibrous tumors of the uterus; (*b*) in cases of imperfect involution of the uterus; (*c*) where portions of the ovum have been retained after abortion?

Soap Bark.—The bark of quillaia, a Chilian tree, contains among other ingredients saponin, a principle widely diffused throughout the vegetable kingdom, and which makes an abundant froth with water. It is stated that an infusion of the bark fulfils all the requirements of a mild soap, and further acts as a moderate stimulant and astringent on the skin. It has been used with marked benefit in pityriasis capitis, and has afforded excellent results in chronic ulcers and eczema of the extremities. The infusion is also a valuable remedy for aiding in arresting fetid perspiration and excessive secretion.

In cases involving the face and armpits, the patient is instructed to dip a small piece of sponge in the infusion and carefully mop over the surface once or twice daily. When the hands or feet are affected they should be bathed in the solution nightly, or on alternate nights, according to the condition. When a more active stimulant and astringent effect is required, the tincture of saponin can be employed with much advantage. The tincture is made by extracting the bark by strong boiling alcohol (4 ounces of bark to 1 pint of alcohol). It is miscible with both water and oil, and has the power of dissolving, emulsifying, and removing fats and dirt from the skin. In many diseases, especially in seborrhœa sicca, it is far preferable to the tincture of green soap. It has all the advantages that are claimed for the latter, and at the same time is free from the high diffusive, penetrating, and destructive action on the tissues that the latter possesses. This tincture has been used with great benefit, not only in diseases to which the infusion is applicable, but also in general thinning and loss of hair in different parts of the body.

Tincture of quillaia also possesses very active powers as an emulsifying agent, and appears likely to occupy a useful place in pharmacy for that purpose. Mr. Collin (*Phar. Jour.*, September 20, 1879) has prepared with complete success emulsions of a number of substances, such as chloroform, fixed oils, copaiba, etc.

The following formula for mistura filicis maris is adopted at Guy's Hospital:

℞ Ext. filicis liq., ʃʒi;
Tinct. quillaiæ, fʒss;
Syr. zingiberis, fʒss;
Aq. destillat. ad fʒi.—M.

If some mercury be shaken up in a bottle with tincture of quillaia, the metal is reduced to a very fine state of division. It has much the appearance of hydrarg. cum cretâ, and, examined with a lens, is seen to be composed of distinct globules of mercury.—*Dub. Jour. of Med. Sci.*, September, 1880.

Congenital Neurotic Papilloma.—At the recent meeting of the British Medical Association (*British Med. Jour.*, vol. ii., 1880, p. 387), Mr. Wyndham Cottle read a description of the case of a boy whose skin presented lines of dark wart-like growths in the course of certain nerves. These lines were confined to one side of the body and limbs, and the rest of the skin was normal. The markings had existed from birth, and followed the course of the cutaneous branches of the fifth nerve, the internal cutaneous, intercosto-humeral, and saphenous nerves, and also occupied the middle line in front. They were limited to the right side, and were composed of contiguous filiform papillomata, and in structure corresponded to ordinary filiform warts. The lesions were closely allied to ichthyosis hystrix, from which they were separated by being unilateral, following the course of certain nerves, and being attended by no accumulation of epithelial débris, horny plates, etc., from alterations in the sebaceous glands. They probably depended on morbid intra-uterine nerve-influence, akin to the zoster of later life, and formed a striking example of perverted nerve-action in nutrition. Mr. Cottle proposed the designation "congenital neurotic papilloma."

Color-Blindness in the Profession.—At a recent meeting of the British Medical Association seven hundred members were examined on this point: twelve were completely color-blind, six red-blind, and six green-blind, and two were incompletely color-blind, one red and one green,—in all, fourteen. Of four others who were not color-blind it may be said that their chromatic sense was feeble. A large number who presented themselves for examination expressed a belief that they were color-blind whose color-sense was yet found on examination to be normal.

Hirsuties Removed by the Galvanic Pessary.—In a discourse on menstrual insanity at the recent meeting of the British Medical Association, Dr. J. Crichton Browne referred to a case seen in consultation with Mr. Tait, many years ago, in which a bearded lady had been benefited by the introduction of a galvanic pessary. The beard subsequently fell off, and the patient's mental condition, which was that of melancholia, improved so that she recovered completely.

MISCELLANY.

A French Doctor on Gluttony.—Dr. Gaétan Delaunay, in a recent essay on biology, addressed to the French Academy of Sciences, devotes a chapter to the study of *gourmandise*, or gluttony, which, in the opinion of the scientific writer, is more commonly observable in men in proportion as they are lower down in the scale of civilization. Intellectual development and an immoderate love of eating and drinking are rarely to be met with in the same person, those who are most addicted to gluttony being savages, negroes, idiots,—all, in short, whose brains lie dormant. In European countries he remarks that, as a rule, the poor are more given to gluttony than the rich, the peasant than the tradesman, the women than the men, children and old persons than adults, the weak than the strong, fanatics than free-thinkers. According to the learned doctor, the profession or calling in modern French society most remarkable for vivacity at the dinner-table is the clerical profession. First on the list of gluttons, then, he places prelates and priests; second, diplomatists; third, magistrates; fourth, superior state functionaries, such as state councillors and others of similar rank; fifth, bankers and financial men; sixth, independent persons, who live on their incomes in idleness; and last, artists and literary men. Dr. Delaunay's theory is, in a word, that the greater the intelligence, the more the mind is engaged or the brain works, the less disposition there is for gluttony; and, following up this theory, he points out, we presume from personal observation, that among artistic classes musicians, whom he considers to be the least intelligent, are the most fond of good cheer, and in the category of singers tenors are greater gluttons than baritones. With regard to gentlemen of the brush and chisel, it is the painters who are more addicted to inordinate eating than sculptors, painters of what is called *genre* being more *gourmand* than landscape-painters. Women, this young laureate of the Academy tells us, are more greedy than men; milliners, adds the doctor,—who seems to have enjoyed the privilege of penetrating into all the dining-rooms of France,—being decidedly greater gluttons than dressmakers.

Higher Medical Education.—A special committee, in a report on medical matters to the Supreme Lodge, Knights of Honor, say that among the certificates of death "we found a death recorded as caused by 'organic duoyenum of the heart,' a peculiar form of cardiac disease of which your committee have no knowledge; one caused by 'dysphagia on account of closing glottis,' and we are left to conjecture whether or no it was done voluntarily, by due process of law, or a dispensation of Providence; another was caused

by 'congestion of the brain *and* falling from a building:' the primary cause of death we are unable to determine; another, in a little more than three months after initiation, died of the following onslaught of maladies: 'inflammation of neck of the bladder, acute bronchitis, pleuro-pneumonia, inflammation of the left ear, nephritic trouble, and functional cerebral.' Trouble enough to kill an entire lodge."—*Kings County Medical Society.*

Infant Mortality in the Belfast Workhouse.—In reply to a question put by Mr. Arthur Moore, M.P., whether his attention has been called to the statement in Dr. M'Cabe's recent report on Belfast Workhouse, that within the six months from January to June eighty-two infants have died in that institution, and if he would inform the house what percentage of the whole number of infants this represents, the chief secretary replied that the ratio of mortality was thirty per cent. This is nearly as bad as the "Butcher's Bill" of the old Foundling Hospital in Dublin, in which institution ninety-two per cent. of all the infants were annually made away with for a long series of years. Subsequently Mr. Moore gave notice that next session he would move a resolution demanding a reform of the Irish poor-law and its administration.

Xylotherapy.—At a recent meeting of the Société de Thérapeutique, M. Dujardin-Beaumetz read for M. Jourdanis a note on the æsthesiogenic properties of certain woods applied to the skin, which he calls xylotherapy (*La France Médicale*). M. Jourdanis has applied plates of wood to the insensible skin, and, as with plates of metal magnets, sinapisms, and blisters, has obtained a return of sensibility. The application of wood seems to be more active than the other means. All woods do not act with equal intensity, and with regard to their efficacy may be classified in the following order: cinchona bark, thuja, rosewood, mahogany, pitch-pine, walnut, maple, apple; poplar, ash, and plane produce no effect. Return of sensibility is accompanied by congestion of the skin. We cannot suppose these phenomena to be caused by electric currents.

Epilepsy from a Foreign Body in the Ear.—Dr. Katz, of Berlin (*La Presse Médicale Belge*), had recently under his care a woman, æt. 30, who had never shown the least sign of hysteria or any other disease of a nervous origin. For a year she had had very troublesome noises in the ear, and about the same time became subject to epileptiform attacks at intervals of one or two months. All the means employed to cut short these attacks were fruitless. When Dr. Katz saw the patient, at the end of last year, he was not long in discovering at the bottom of the left auditory meatus a black mass, which was extracted with some difficulty, and was found to consist of a roll of cotton wool covered with cerumen. Freed from this foreign body, the woman found herself relieved at the same time of the disagreeable sensations in the left ear and the convulsive fits.

Mutual Aid Association of the Philadelphia County Medical Society.—On Thursday, 16th ult., the first social reunion of the association was held at the residence of the President, Dr. Benj. Lee, Manheim Street, Germantown. In addition to the members of the Society, a number of prominent physicians were present by invitation. The entertainment lasted from four till eight in the evening, and the company spent an exceedingly pleasant time in the spacious grounds (some sixteen acres in extent), the enjoyment being heightened by a delightful concert performed by an orchestra, the illumination of the gardens after dusk, and a bountiful attention to the necessities of the inner man. The pleasure of the event was enhanced by the sedulous attention shown to his guests by Dr. Lee's accomplished family.

The Teaching of Obstetrics.—In a discourse on this subject before the British Medical Association (*Brit. Med. Jour.*, vol. ii., 1880, p. 375), Dr. Macnaughton Jones stated the three following propositions: 1. The efficient teaching of an obstetric class cannot be effected in a course of less than one hundred lessons. 2. An attendance on at least twenty cases of labor should be required of the candidate before he is permitted to present himself for his final examination, these cases to be attended in some recognized hospital or maternity or under the supervision of a recognized teacher. 3. The candidate should be required to produce proof, by notes of cases or otherwise, that he has attended in the wards or exterior department of a hospital a given number of uterine cases.

A Positive Sign of Early Pregnancy.—Dr. J. H. Caritens, in the *Detroit Lancet* for September, calls attention to the color of the mucous membrane of the vagina and cervix uteri as a positive sign of pregnancy during the first three months.

He says, "This I have always found of a purplish blue, or rather deep violet hue, in pregnant women, and I have depended on this peculiar color in making a diagnosis of pregnancy in the first, second, and third months. I can say it has never failed, and it is not produced by any pathological condition: the different colors produced by uterine disease cannot be mistaken for this pathognomonic violet hue."—*Maryland Medical Journal.*

Treatment of Pseudo-Membranous Colitis by Euonymin.—Dr. Blondeau brought before the Société de Thérapeutique recently (*La France Médicale*) a case in which he had employed euonymin in one of his patients suffering from pseudo-membranous colitis which had been vainly treated by the most energetic remedies. He prescribed—

euonymin, 0.05 gramme; extract of hyoscyamus (B.P.), 0.10 gramme, made into two pills, one to be taken morning and evening. After six days of this treatment, the patient had regular motions, and recovered her health, which she had lost for some months.

PRE-NATAL IMPRESSIONS. — An English medical paper says that a Maryland physician reports the case of a lady who, during pregnancy, carried with her a pocket edition of Moore's Poetical Works, which she read almost constantly. Her child, at three years of age, exhibited a most wonderful gift of putting sentences in rhyme,—in fact, naturally expressed his little ideas and thoughts in flowing measure! Blame not the bard; but a case like this shows how important is a well-assorted library to a gravid uterus.

THE END OF TWO BOGUS COLLEGES.— Replications were recently filed in Court of Common Pleas, No. 3, to answers submitted by the "Eclectic Medical College of Pennsylvania" and the "American University of Philadelphia." The answers of the defendants set out that they claimed to exercise their rights, privileges, franchises, etc., by virtue of an act of Assembly, dated March 26, 1867, incorporating the latter college, and an act of February 25, 1850, incorporating the former.

It was to these answers that counsel for the Commonwealth filed replications. They aver that the above corporations have forfeited their charters, because of, first, the conferring of degrees upon persons not possessing the qualifications such as are prescribed by their charters; second, the sale of diplomas; third, the granting of degrees of doctor of medicine, and antedating such diplomas in order to make it appear that the recipients had the right to practise medicine; and, fourth, the issuing of diplomas with forged signatures. After the replications were filed, counsel for both of the defendants confessed judgment of ouster in favor of the Commonwealth, and filed as a part of the record a letter from Dr. Buchanan authorizing him to do so.

PORRO'S OPERATION SUCCESSFULLY PERFORMED. — Dr. Elliott Richardson, of this city, recently performed Porro's operation successfully, the mother being a well-known dwarf only forty-two inches in height and thirty-two years of age. This is the first successful operation of the kind which has ever been performed by an English-speaking surgeon.

FALLING OF THE HAIR.—Mr. James Startin, in the *British Medical Journal*, suggests the following application in general loss of hair without obvious cause:

℞ Vaselini,
Ol. ricini, āā ℥ss;
Hyd. ox. rub., gr. v;
Liq. ammon. fort., fℨss;
Ol. rosmarini, gtt. v.—M.

THE death of Prof. Polli, famous for his researches upon fermentation, is announced.

CHOLERA has broken out at Saratov, on the Volga, and at Orel, in Russia.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM SEPTEMBER 19 TO OCTOBER 2, 1880.

IRWIN, B. J. D., MAJOR AND SURGEON. — Relieved from duty in Department of Dakota, and to report in person to the Lieutenant-General commanding Military Division of the Missouri, for duty as Attending-Surgeon at Headquarters of that division, relieving Surgeon Spencer. S. O. 205, A. G. O., September 24, 1880.

SPENCER, W. C., MAJOR AND SURGEON.—When relieved by Surgeon Irwin, to report in person to the Commanding General, Department of Dakota, for assignment to duty. S. O. 205, c. s., A. G. O.

GODDARD, C. E., MAJOR AND SURGEON. — To report in person, at the expiration of his present leave of absence, to the Superintendent Mounted Recruiting Service, for duty as Post-Surgeon at the Cavalry Depot, Jefferson Barracks, Mo. S. O. 205, c. s., A. G. O.

BROWN, J. M., CAPTAIN AND ASSISTANT-SURGEON.—To accompany battalion Sixteenth Infantry from Cantonment on the Uncompahgre, Col., to Fort Garland, Col., and there remain on duty. S. O. 211, Department of the Missouri, September 22, 1880.

BREWER, J. W., CAPTAIN AND ASSISTANT-SURGEON.—To report in person to the Commanding General, Department of the South, for assignment to duty. S. O. 205, c. s., A. G. O.

TREMAINE, W. S., CAPTAIN AND ASSISTANT-SURGEON.— Relieved from duty in Department of the Missouri, and to report by letter, at the expiration of his present sick-leave of absence, to the Surgeon-General. S. O. 205, c. s., A. G. O.

MUNN, C. E., CAPTAIN AND ASSISTANT-SURGEON.—To accompany the battalion of the Fourth Cavalry, which is relieved from duty with the Ute Expedition, to Fort Garland, Col., and then proceed to and take post at Fort Hays, Kansas. S. O. 210, Department of the Missouri, September 21, 1880.

WEISEL, D., CAPTAIN AND ASSISTANT-SURGEON.—To report in person, at the expiration of his present leave of absence, to the Commanding General, Department of the East, for assignment to duty. S. O. 205, c. s., A. G. O.

HARVEY, P. F., CAPTAIN AND ASSISTANT-SURGEON.— Assigned to duty at Fort Snelling, Minn. S. O. 113, Department of Dakota, September 22, 1880.

WINNE, C. K., CAPTAIN AND ASSISTANT-SURGEON.—Relieved from duty at Fort Brady, Mich., and assigned to duty as Post-Surgeon at Fort Schuyler, New York Harbor. S. O. 167, Department of the East, September 21, 1880.

REED, W., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Ontario, N.Y. S. O. 167, c. s., Department of the East.

BIART, V., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.— Relieved from duty in the Department of the Missouri, and to report in person, at the expiration of his present sick-leave of absence, to the Commanding General, Department of Dakota, for assignment to duty. S. O. 205, c. s., A. G. O. The operation of above order suspended until May 1, 1881. S. O. 209, A.G.O., September 30, 1880.

RICHARD, CHARLES, FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty at Fort Snelling, Minn., and assigned to duty as Post-Surgeon at Fort Maginnis, M. T. S. O. 110, Department of Dakota, September 15, 1880.

BENHAM, R. B., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Assigned to temporary duty with escort to working-parties on extension of Northern Pacific Railroad at Camp Houston, D. T. S. O. 113, c. s., Department of Dakota.

PHILADELPHIA, OCTOBER 23, 1880.

ORIGINAL COMMUNICATIONS.

THE ETIOLOGY OF FRACTURES OF THE CRANIAL BASE, AND THE ANATOMICO-PATHOLOGICAL REASONS FOR THEIR FATALITY.

BY C. B. NANCREDE, M.D.,

Surgeon to Episcopal Hospital; Lecturer on and Demonstrator of Osteology and Syndesmology in the University of Pennsylvania.

Read at a Meeting of the Pathological Society of Philadelphia, September 23, 1880.

GENTLEMEN,—When asked to prepare a paper for this evening, I felt how utterly inadequate was the time which remained before the 23d of September, in which to write one worthy your consideration. As one of the authors of the amendment to the constitution whereby the conversational meetings were inaugurated, I felt, however, that it would ill befit me to refuse to fill the gap left by the declination of one so much better fitted for the task as my friend Dr. J. Ashhurst.

Upon due reflection, the subject with which I propose to occupy your attention this evening has seemed eminently fitting for the purpose, and for the following reasons. Although, of course, to some the views I intend advancing are neither altogether new nor original, yet, to judge by the literature of the subject, few practically realize their importance.

Let it be clearly understood that the major part, if not all, of what I propose saying is not original; but, owing to the seeming ignorance of most writers upon the subject, the old views need re-stating. The ordinary view held, and, judging from the results, taught, is that these injuries are so grave from the amount of violence causing them, or from the important vital structures contiguous to the injured bones and liable to similar traumatic lesions. Now, I would state, at the outset, that I consider this view to be very incorrect, and that could we change the structure of the skull so as to render its *base* like its *vault*, extensive shatterings could not occur; or, if they did, no more evil results would follow than in an ordinary fracture of the vault. When my explanations are given, this apparently bold statement will appear, I trust, justified; although, strictly speaking, it is only approximately correct. It is, however, sufficiently accurate for the sake of impressing what I believe to be an important fact.

Of course it will be understood that I do not deny that death is the direct result of basal injuries when they are such complete crushes as to divide the brain-case into several distinct segments, with extensive lacerations of the brain-substance. Perhaps the clearest way to explain my views will be to take a case such as I have seen myself, or such as Hilton relates, as a text.

First, however, let us classify the various basal fractures, and then define clearly which are dealt with in this paper. First, then, we have fractures of the base resulting from direct violence, such as a thrust from a cane or umbrella in the orbit. A violent blow on the nose, which fractures its bones, may also break the cribriform plate of the ethmoid, as in these specimens which I show you. Then, too, the condyles of the lower jaw have been driven through the glenoid fossa of the temporal bone by direct violence applied to the former. Besides such instances of direct violence, there are others where I maintain that it is in reality the fracturing force. I suppose that many will take exception to this statement: still, it is true, and is constantly taught, although not formulated as I have done. Suppose a man falls from a great height upon his feet, what results? Why, practically, the condyles of his occipital bone are struck violently through the medium of the spinal column,—more violently, indeed, than otherwise could occur, because plus all the amount of the vibrating structures of the body, except such as are diverted or checked by the various tutamina, struck just as *directly* for mechanical purposes as if with a sledge-hammer.

Again, if a man falls from a height and strikes full upon the vault in some comparatively yielding substance, as soft earth, the weight of the body again strikes, through the medium of the spine, a violent blow upon the occipital condyles, thus fracturing them. This statement of such injuries being due to direct force may appear clearer if I say that a blow is merely the exciter of vibrations, and that we must consider the point whence they start as in reality the *point of impact.*

Then, again, a third class present themselves, where the fissure starts in the vault and merely reaches the base by direct continuity. The head may be also caught between two opposing forces, when a general crush involving the base will ensue. Finally, we have those said to be produced by *contre-coup*. If we mean by this a fracture upon the side opposite to the point struck, unless this point be about the centre of the vault, this certainly is unlikely. For instance, a violent blow upon the right parietal boss will not produce a fracture at the left parietal eminence, but at the base of the cranium, through one or both petrous bones. I do not deny that a blow in this situation may produce laceration of the brain-substance exactly opposite to the point struck, because the brain is practically homogeneous, and vibrations *cæteris paribus* are conveyed through it equally, while the skull *does not* convey vibrations equally well in all directions. Again, the statement that the vibrations which are excited in the vault travel by the shortest route to the base is absolutely incorrect. They reach the base by the "shortest anatomical route," indeed, but that is very different from the shortest route, and is often quite a long one. Again, the statement made by a recent author that a blow upon the occiput may break the petrous portion of the temporal bones, because the "basilar process rests against the apices of these petrous bones," is a mistake, as the force which breaks these bones does not reach them through the basilar process, but the vibrations pursue another course, as will be presently explained.

The mistake here made is in failing to remember that the various portions of the skull are of varying thicknesses and are so constructed for specific ends. If the vault were of even thickness and density, as well as all of the base except its central portion, and if the skull were also a true sphere, *then* true fracture by *contre-coup* of the base would obtain, for the vibrations would travel from the point struck equally in all directions until, meeting at the weak central basal portion, it would be disrupted. But the skull is of unequal thickness, it is not a sphere, and certain portions of its base, although frequently broken, are in reality the densest and strongest.

It is unquestionably true that the portion of the skull struck determines which of the fossæ of the cranial base the fracture will traverse. This I hope to explain by certain anatomical peculiarities of the skull-structure. This fact relative to the point struck determining the site of the fracture, has been proved by the experiments of Aran and the investigations of Prescott Hewett.

Some writers have been so hard pushed to explain fractures at a distance from the part struck, that they have actually ascribed them to the vibrations communicated to the *brain*, which then acts as the fracturing force. Thus, Prof. Longmore considers that certain fractures of the orbital plates of the frontal bone, caused by gunshot wounds of distant parts of the skull, are actually produced by the vibrations of the brain. In this view Otis concurs. Dr. Harrison Allen, in an article on fractures of the cranium, in Hays's *American Journal of the Medical Sciences* for January, 1874, gives an explanation of such cases, instancing that of President Lincoln. I regret to feel compelled to dissent from his conclusions. In the proper place the case will be related, with Dr. Allen's comments upon it, and my own reasons for dissent.

Before proceeding to the anatomical demonstrations which I wish to make, let me refresh your memory by a homely illustration as to the direct proportion of the force of vibrations to the amount of the bony or other tissue struck. If one end of a wire of fine calibre be held in the hand, and the other, after being laid upon an anvil, be struck never so hard, no appreciable vibrations will be perceived; yet they are present. Let the same experiment be tried with a crow-bar, and I think few of us would care to suffer the unpleasant jar that would result. Now, just this same thing occurs in the skull: where thin the vibrations are imperceptible, where thick they are marked. But the base of the skull, having to support the superincumbent weight of the skull and brain and afford a firm basis for the movements of the lower jaw and of the head on the spine, as well as to protect the important nervous structures connected with it, must be massive, at least in parts. These advantages during health have compensating disadvantages when man is subjected to violence: indeed, in his ordinary movements this massiveness of portions of his cranial base would be very disad-

vantageous were it not for certain wise provisions presently to be spoken of. It is hardly necessary for me to refer to the ordinary tutamina of the brain, such as the hair, scalp, pericranium, and dura mater, acting, as the latter two do, as a wash-leather lining and cover would to a bell. It will, however, be essential to speak of certain processes of the dura mater.

I will now give briefly a history of a case of fracture of the base, which I propose to use as my text, in conjunction with the general relation of similar cases given by Mr. Hilton in his remarkable lectures upon the cranium. My friend Dr. Charles Wirgman called upon me one evening some months back, requesting me to see in consultation with him a young boy of some nine to ten years, who, he thought, was suffering from a fracture of the skull. I am indebted to Dr. Wirgman for the following outlines of the case. Four days previously he had been desired to see the patient, who had walked home, assisted by his playmates, after having fallen on his head while playing leap-frog. When Dr. Wirgman saw him, he was suffering from slight symptoms of concussion, the exact details of which are of no moment. The following day he seemed better, only complaining of some headache. Upon the third day the improvement was *very* marked, nothing remaining but some headache. He was very desirous of being allowed to sit at the window, and I know that the doctor's injunctions as to perfect quietude were not complied with. The patient, when called upon to evacuate his bowels, went out as a matter of course to the yard, and walked about the apartment when so inclined. Only a few hours after Dr. Wirgman's last visit he was hastily summoned; but before going he called upon me to request my advice and assistance. The patient's residence was at a short distance, but when we arrived he had been dead some little time. He had been—as far as could be ascertained—attacked with vomiting, which was followed by eclampsia, rapidly terminating life. I expressed the opinion that the patient had had a fracture of the base of the cranium, and that perfect quietude might possibly have averted the fatal results. By the courtesy of Dr. Wirgman and Dr. Lee, the then coroner's surgeon, I was present at the autopsy. An insignificant ecchymosis was detected over the right mastoid region, which, it is probable, resulted from infiltration of blood from the fracture. Upon reflecting the skin, what at first sight looked merely like the normal masto-occipital suture, with a little coagulated blood occupying its depressions, was seen. Upon a closer scrutiny this proved to be a fracture separating the synarthrosis. The test upon which I relied was the impossibility of removing the line of coagulated blood effused between the fragments, while the same collected in a suture can always be wiped or washed away. Upon removing the calvarium, a line of fracture was discovered which traversed the right petrous bone, extending posteriorly from the occipito-mastoid suture forward. A small blood-clot of a few lines in extent lay near the fracture, but there was nothing that could be called meningitis: indeed, the brain and its membranes were unusually healthy-looking.

Hilton makes the following pertinent remarks, which I transcribe verbatim:

"I have known it to happen that a person, having been exposed to external violence, which has led to a fracture of the base of the skull, and feeling pretty well a few days after the accident, has expressed a desire to get up and leave his sick-chamber, which his medical attendant has been indiscreet enough to allow him to do, or which he has done of his own accord, without the knowledge or consent of his medical adviser. After moving and walking about, however, for a short time, he has soon complained of headache, has been attacked with sickness and vomiting, afterwards has had confusion of his ideas, and, finally, has fallen into a state of unconsciousness, in which, after three or four days, he has expired."

The first point of mechanical interest in the structure of the brain-case is its ovoid form, to which is ascribed a large proportion of the security of the brain. To a considerable extent this is true; but it is a matter of profound surprise to me how one important point is apparently completely overlooked. Take up any work upon anatomy, and the author will doubtless expatiate upon the strength secured by the peculiar form of the brain-case, any segment being a section of a spheroid. If an injury—as a fracture—were only produced by a *crushing* force, this would be an incontrovertible proposition; if, upon the other hand, a large

part of the damage is done by setting up *vibrations* in the bones themselves, then the form of the skull only conduces in a slight degree to its immunity from fracture. An arch that will sustain uninjured hundreds of tons' *pressure*, if vibrations are set up in it, may be readily *fissured* in many directions, although its *form* may remain unchanged. The arched form of the skull, then, merely resists the tendency of the bones to be pressed inward when a blow is struck; after that the fracturing force expends itself in producing vibrations, which cause the fracture. Any brittle body capable of fracture will be so injured whenever the *vibrations become violent enough to overcome the cohesion between the particles composing that body.*

Let us first examine the anatomy of the child's skull, as it may give us some hints which will prove useful. I suppose that I may safely say that the base of a *young* child's skull has never been fractured by anything but direct force, or that more than *one* bone of the vault has ever been broken unless the force was actually applied to it. Now, why is this so? Examine an infant's skull, and you will see that each bone is isolated from every other by membrane,—than which there is no better arrester of vibrations. Again, as you will readily see by a careful examination of any young parietal or frontal bone, but specially of one say at the sixteenth week *in utero*, the most projecting portions (those, of course, which are most apt to strike the ground first in a fall) are the thickest, while extending from these centres are radii of bone becoming more and more delicate. Each of the fine terminal points of these radii is enveloped by the membrane, which, by its ossification, forms the bone. Recall now my homely illustration of the vibrations of the wire and the crow-bar. Do you not see that the vibrations start in the denser bone, but, being conducted on, are propagated by thinner and thinner bone (*i.e.*, a structure less and less capable of vibrating strongly), until they are finally safely conducted off to the terminal radii of the bone, which are *completely enveloped in membrane*, and are thus totally arrested? By this you can readily see that the injury inflicted upon one bone of an infant's head by a blow never passes beyond the one bone struck.

These efficient means for the arrest of vibrations explain the immunity from injury enjoyed by infants and children, where, considering the strength of their skulls, the injuries they receive with impunity are otherwise inexplicable. This is, indeed, fortunate, when we consider how "mobile" is the nervous system of the infant, and how seriously injuries of it are resented.

What, therefore, should we learn from this? That one of the most efficient means for arresting vibration in bone is to have it enveloped closely by a membranous tissue.

Turning to the adult skull, I would call your attention to the following points. The projecting parietal bosses, with the frontal eminences, are not so prominent, and, instead of being the thickest portions of the vault, they are often the thinnest. The eight component bones of the brain-case are more or less co-ossified, and are in bony contact. Let us remove the calvarium of both the infant and the adult. In the infant the various bony projections are certainly present, but the brain looks as if it would fit fairly. The base of the adult's skull looks as if nothing could be better fitted to lacerate the delicate brain, and is not at all correspondent in form. Here in front are the projecting anterior clinoids, there behind the posterior projections of the same name; here is a deep depression, there an elevation. If a cast of the base of the brain were taken, it would plainly show that there exists but little correspondence between this portion of the case and its contents. A blow on this practically solid ovoid of bone formed by the skull will infallibly set up vibrations, which will pass in any and every direction. Here is an organ of delicate structure which apparently has to lie upon a rugged and uneven bed. The ordinary motions of walking, much more those of running or jumping, would apparently imperil the integrity of the vital nerve-centres. What, then, upon the whole, renders the brain the best-protected organ in the body? Again let me say that the hair, scalp, etc., are excluded from consideration as tutamina in our present remarks.

The mechanical effect of the diploë, however, must not be ignored, especially in view of some statements with regard to it made by Dr. Allen in the paper already cited. In the first place, he denied the correctness of the usual descriptions of

there being two tables of compact tissue in the skull. On the contrary, he maintains that there is but one, viz., the internal, and that the so-called external table is only modified cancellous tissue.

I cannot agree with him, for, call it what you may, it is still a much more compact, dense structure than the subjacent diploë, and as such a vastly better conductor of vibrations. On the other hand, I entirely agree with him in thinking that the inner is the best and principal conductor of vibrations. Again, Dr. Allen cites the easily demonstrable fact that there is an actual absence of the diploë in certain portions of several of the cranial bones. The sites specially to be noted where this important element is absent are the cerebellar fossæ, the roof of the glenoid fossa, the greater part of the squamous plate of the temporal bone, the orbital plates of the frontal, and the floor of the lateral sinuses, as they approach the base of the brain. Here also my views clash with those of the author cited. He says that in these situations the internal and external tables are in contact, or, more correctly, that *both* diploë *and* external tables are absent. The importance of this will appear when he goes on to say that a blow struck upon any portion of the skull, if not of sufficient violence to pass the damper of the diploë to the internal table, is conducted to more distant points along the diploë itself, not by the external table, which he maintains does not exist. For me, however, it does exist, and is of great importance, for the following reasons. By Dr. Allen's explanation, both in injury and in the ordinary normal movements the slighter vibrations are confined to the diploë, while the more violent simply do damage by affecting the vitreous table despite the diploë and plus whatever vibrations may be present in the latter. I, however, would liken the two tables to two insulated wires, the insulating medium being the diploë. As long as the diploë is present, either of the two tables may vibrate separately, or both in differing degrees. At those places, however, where the diploë is absent, the two conductors of vibrations are in contact and the circuit is completed, the spark leaps across, and we have a shock; *i.e.*, to return from illustration to fact, the vibrations of differing intensity meet, and a fracture takes place, subject to certain modifying influences next to be referred to.

To return to our question, What renders the brain the best-protected organ of the body? This was when speaking of the apparent want of adaptation between the base of the brain and of the brain-case. The answer is, these very irregularities and projections, which seem fitted only to lacerate the delicate structures lying superimposed. Just where the greatest dissimilarity exists between the brain and its case, viz., in the central portion, in the normal state, the brain is distinctly lifted off from the bones by a stratum of fluid,—the cerebro-spinal fluid,—which serves, as Mr. Hilton points out, as a "water-bed." By means of this the cerebellum does not come into contact even with the posterior cerebral fossa, and the central portions of the cerebrum are held off at a distinct interval from the bones. Some such provision is absolutely necessary for the ordinary normal movements to proceed in safety. Without something similar, even walking—much more running and jumping—would inevitably result in fatal laceration of the brain-pulp. But its usefulness does not end here. What better means of arresting vibrations originating in the bony parietes which might otherwise prove prejudicial to the brain? Surely, nothing.*

Let me pass around this specimen of the base of the skull with its calvarium. By holding it up to the light you will see that there are certain thin portions mapped out by certain thicker ridges. This will be clear from the different transmission of the rays of light. These thicker portions, in general terms, converge towards the petrous portions of the temporal bone, the anterior and posterior clinoid processes, and the crista-galli of the ethmoid. Examine now with me the anatomical peculiarities of the parts mentioned. The anterior clinoids are surrounded by dura mater, and are immersed in the cerebro-spinal fluid. The same description will answer for the posterior clinoids. The apex of the petrous portion of the temporal bones, and a portion of their inner margins, seem, the former in contact with the sphenoidal body, the latter with the basilar process of the occipital bone. In reality, the apex of the petrous bone is separated from the body of the sphenoid by the plate of cartilaginous tissue filling the foramen lacerum medius, while the inferior petrosal sinus lies in a groove

* Of course the vibrations which meet at the base of the skull may neutralize one another.

formed partly by the petrous and partly by the basilar process of the occipital bone. Finally, the crista-galli is the point of attachment of the falx cerebri, in the commencement of which it is embedded. Let the skull now be set in vibration by a blow, and, instead of reaching the base by the "nearest" route, the vibrations will follow the nearest one, or *all*, of these *anatomical* routes.

I think, then, that I have demonstrated that these apparently useless and dangerous projections have a useful purpose, for each serves as the terminal discharge-point for the accumulated vibrations which *must* follow, by virtue of mechanical laws, the best *conductors*, viz., the densest portions of the bone,* which have been all stated to converge to the points mentioned. These points are provided with such efficient dampers of vibrations that all the ordinary and many of the extraordinary vibrations are rendered innocuous. Indeed, had this properly come within the scope of my paper, I think I could demonstrate that the ordinary vibrations are positively put to a physiological use.

Let me now apply the knowledge gained from these anatomical studies to the question of fracture of the cranial base.

The statement, then, made by Aran and others—that fracture of the base is invariably accompanied by a fissure of the vault, which in reality is the starting-point of the fracture—is, I think, incorrect, from the foregoing facts as to the conduction of vibrations, even if we exclude these specimens and the case I have related. If Aran's view were correct, the greatest force being applied at the weakest portion of the skull, viz., the vault, the fissures should be widest apart at that point, becoming smaller and less widely separated as they reach the denser and stronger positions of such bones as the petrous; but the reverse obtains. In proof of my statement, examine this skull. Again, the case taken as my text and the two specimens that I show you here, besides other recorded cases, show that in the slighter cases of fracture of the base the vault is not fissured. Now, if fracture of the base does occur in these cases without fissure of the vault, severer ones, where the vault is so injured, I consider, can be caused in the same way; but, the force exerted being greater, the fissures starting at the base simply extend farther, and thus implicate the vault. The separation of the masto-occipital suture in the three cases cited—mine and these two in the Mütter Museum—seems to give the key to the mechanism of the severer fractures. It would be impossible to produce this effect if the fracture started at the vault, unless the upper continuation of the same suture were separated, and that, too, more widely than below. Presenting the appearances seen, the injury must have been produced by a spreading force acting somewhat in the way moistened beans do in separating a skull. If the fracture of the base started in the vault, the suture could be separated only by fracturing it so as to drive one bone below the level of the other; but this is *not* the appearance found. If, on the other hand, it commences at the base, the vibrations fracture it, and, displacing the bones, the lower part of the masto-occipital suture would be—as it is—*forced apart from within.* This is clearly the case in the specimens that I show you, and in the case related. I believe that this is *always* so, and that the appearance in the three cases cited is the key to the whole subject.

By examining the phenomena presented by contusions of the brain, an additional proof will be found of this conduction of vibrations to the points mentioned. Prescott Hewett states that the *under* surface of the cerebellum is the part of that organ most frequently contused; that the posterior lobes of the cerebrum, resting, as they do, upon the tentorium, are but seldom injured; that the anterior lobes are more frequently so; but that the middle lobes are vastly more frequently contused. He explains these facts by the relative frequency of fractures in the various regions and the numerous sharp, irregular projections of the cranial base, "which, although rounded off to a certain extent, and smoothed down by the dura mater, are still both sharp and numerous." Now, as contusion is frequently found in various portions of the brain *without any fracture*, and as even in fracture of the base the fragments themselves do not usually injure the brain, the only explanation left is to consider them as largely due to the conduction to that point of powerful vibrations. As to the statements concerning the sharp points, etc., I can only refute them by again calling your attention to

* The dense ridges of bone described are also actually amplifiers of vibrations.

the actual preparations before you, together with the position of the cerebro-spinal fluid. How Mr. Hewett and M. Fano can make such statements after examining a skull in the fresh state passes my comprehension. They have eminent authority, however, to fall back upon, whose want of observation still more surprises me,—viz., Sir Benjamin Brodie, who says, "The great irregularities which exist on the inner surface of the basis of the cranium sufficiently explain wherefore the inferior is more liable to be ruptured than the superior surface of the brain." Mr. Hewett adds, "And nothing could be more explicit." It is only *explicable* to me by supposing that they examined—as is much too customary—only the *dried*, not the fresh, skull.

Let us examine President Lincoln's case, similar ones to which are explained by Longmore in the following manner: The lesions are to be ascribed to a "transmitted undulatory stroke or sudden impulse of the brain-substance itself against the thin bony layers constituting the orbitar plates. I am in possession . . . of the notes of a case in which a similar fracture took place in one orbitar plate, from a ball passing along only grooving the upper surface of the hemisphere lying over the plate broken." Dr. Otis, as before said, accepts Prof. Longmore's opinion as being more satisfactory "than the hypothesis that the fracture was produced by *contre-coup*. The unusually thin orbital plates on either side were exposed to the impulse of the cerebral pulp. Even if they were not fully protected from the vibrations in the vault of the cranium by the dense supra-orbital ridges, it might be inferred that the force would be transmitted mainly to the right orbital region, or that opposite the entrance-perforation, whereas *both* orbital plates were fractured."

Dr. Allen also quotes Prof. Longmore's reasons for thinking that the shock could not be transmitted along the cranial walls to "the expanse of the frontal bone itself and the several processes within which the orbital plates are held, and by which they are so strongly protected in all directions laterally." As I have just said, my study of the cranium leads me to a very different conclusion with regard to Lincoln's fractured base from that of Dr. Allen. Let me quote his own words: "Now, in the case of President Lincoln, the ball, not expending its force about the wound of entrance, yielded the greater part to both tables of the cranium. The outer diploic layer appropriated the vibrations, and transmitted them to the great wings of the sphenoid bone, and thence to the axis of the cranium, without injury to the skull. The inner plate, not having any means of diverting its burden of force, carried it forward in two different lines from the wound of entrance to the orbital plates (which lie, as is known, about on a level with the upper margin of the tentorium), and broke them. It is to be inferred that, had the ball entered either above or below this line, the conduction of waves towards the forehead would have been greatly modified." How it is possible for the orbital plates to be protected from vibrations by the "dense supra-orbital ridges" I cannot see, nor why the "right orbital plate" should be more likely to be broken, except upon the old exploded theory of *contre-coup*, is not plain. Again, Prof. Longmore, with Dr. Otis, seems to misapprehend a most important mechanical fact. If the force which breaks the orbital plates be of the nature of a something from without, entering between the particles of the bone and pressing them asunder, *then* the "expanse of the frontal bone," the "several processes within which the orbital plates are held, and by which they are so strongly protected in all directions laterally," and the "dense supra-orbital ridges," might perhaps avail. The truth is, however, that it is the vibrations of the bone itself which become so marked as to overcome the cohesion between its particles, and some, if not all, of the same dense bony ridges are the means by which these disrupting waves reach the orbital plates.

It is stating a mechanical impossibility to say that the vibrations were carried "forward in two different lines." As well might one expect a pebble thrown into water to send ripples in but two directions. The truth is, that the ball, entering one inch to the left of the median line, just above the left horizontal arm of the occipital cross, started vibrations which passed in *every* direction. If, however, the views are correct which I have just explained, the vibrations soon met with the thickened margins of the groove for the superior longitudinal sinus, which, being the best conductor and reinforcer of them, carried them to the frontal bone and crista-galli. The usual damper of vibrations here was

insufficient, and, they being propagated through the anterior fossa, the weaker parts of the latter gave way. Doubtless, too, vibrations reached the orbital plates through the lesser wings of the sphenoid, and were coefficient in producing the fracture. On the other hand, those passing downward were safely conducted off by the means already indicated when speaking of the course of the vibrations.

A valuable fact pointed out by Prof. Allen is, that the occipital condyles really consist of two facets, often entirely separated from each other by a distinct groove, and he points out how if, at the time of force being applied, say from a fall on the feet, the head be extended, the force will affect chiefly the posterior facets, while if the head be flexed the anterior ones will have to bear the brunt. This probably explains, always subject to the laws of conduction of vibrations, why in one case a fall on the feet produces a fracture of the anterior, and in another a fissuring of the posterior fossa.

Finally, we come to the reasons for the fatality of basal fractures. Of course, in the extensive tremendous crushes frequently found no explanation is needed. But recall to mind the cases I have related where the injury was so slight as almost to produce no symptoms at first; where the contusion of brain-substance, if such existed, was at a minimum; where, in my own case, no inflammatory symptoms were present. Here, clearly, some explanation is demanded. As long as such patients are quiet, as long as no vibrations are excited by the movement of locomotion, just so long the brain-substance contiguous to the lines of fracture remains uninjured. The primary jarring and slight contusion are recovered from; and, should quiet be sufficiently long maintained, recovery ensues. Let, however, the patient, tempted by his apparent recovery, leave his bed, immediately the normal vibrations which must mechanically arise are excited, and what follows? Before, in a state of health, they were safely conducted to points where they were annihilated; but now their course is interrupted by the fissures, and the superimposed brain-substance is jarred and probably slightly lacerated. From such constantly-recurring injuries, slight though they be, results, in the adult, meningitis or encephalitis, in the child, as in my case, very probably eclampsia, due to the greater excitability of the young brain. In proof of these slighter injuries induced by the slighter vibrations, let me again refer to the severer ones seen in extensive shattering of the base. As I then said, upon anatomical grounds, those found in the cerebellum and middle lobes of the brain cannot be produced to any great degree by direct injury from the fragments, but result from the tremendous vibrations conveyed to the brain when the bones gave way.

It must now be clear that the anatomical facts demonstrated show: 1. That vibrations originated at any part of the skull do *not* pursue the most direct course, although they *do* follow the most direct anatomical route, to the base of the skull,—some, indeed, following all the anatomical courses, but the more distant more feebly, owing to the damping effect of the diploë and other tutamina of the brain. 2. That the means for rendering innocuous the ordinary jars of normal motions and many of the accidental blows, when the force applied is excessive, tend to the destruction of certain parts. 3. That fractures of the base much more commonly than is usually taught nowadays start *from* the base and extend thence into the vault. 4. That, when the normal route of the vibrations is interrupted by a fissure, those produced by ordinary normal movement, then being prevented from terminating in their proper dampers, injuriously affect—perhaps even slightly lacerate—the brain-substance, and thus largely account for the greater fatality of such injuries over those of the vault. 5. That these facts should impress us with the necessity for the most rigid enforcement of quiet in cases where we suspect or are certain of a fractured base, where quietude must be maintained for a lengthened period.

TUBERCULOUS LARYNGITIS.—When there are great pain and dysphagia, the following mixture, applied with a laryngeal brush, is recommended by Dr. E. Fletcher Ingalls. The relief produced by the application of this has given more satisfaction, says Dr. Ingalls, than anything else in the course of his professional life:

℞ Morphiæ sulph., gr. iv;
Tannin, gr. xxx;
Acid. carbolic., gr. xx;
Glycerin., ℥j.—M.

New York Medical Record.

HEMORRHAGE INTO THE BASAL GANGLIA, FOLLOWED BY EFFUSION OF BLOOD INTO AND BEYOND THE VENTRICLES, SYMPTOMS AND LESIONS OF APOPLECTIC SHOCK, CHEYNE-STOKES RESPIRATION, HIGH HEAD-TEMPERATURE, ETC.

Read before the Philadelphia County Medical Society, September 22, 1880,

BY CHARLES K. MILLS, M.D.,

Neurologist to the Philadelphia Hospital; Visiting Physician to the Norristown State Hospital for the Insane.

G. H., aged 62 years, while eating his dinner, suddenly fell unconscious. For several months before he had at times complained of dizziness and queer feelings in his head. His radial and other vessels were hard, and evidently the seat of degenerative change. When first seen by Drs. Allison and Gibb, two of my internes at the Philadelphia Hospital, a few minutes after the attack, he was profoundly unconscious, his breathing being puffing.

At this time marked right-sided paralysis was present. In the face, both the upper and lower fibres of the facial were involved; the eye remained partly open, and the mouth was pulled decidedly to the left. The right arm and leg were also powerless.

The patient was seen by me two hours after the onset of the attack. He was lying on his back, unconscious. The loudest shouts had not the slightest arousing effect. His face was pale. His left eye remained closed, but the eyelids of the right side did not come quite together. The pupils were equal; they were sluggish, but neither dilated nor contracted. Conjugate deviation of the eyes was not present; his eyes were directed straight forward. On irritating the conjunctivæ, a good reflex response was elicited. The mouth was drawn very slightly to the left,—so little that it needed careful observation to determine the fact. The right nostril was more dilated than the left. As far as general appearances went, little difference in the paralytic condition could be made out between the limbs of the right and left side: close examination, however, showed a more profound paralysis of the right arm and leg than of the left extremities; he occasionally moved the left arm and leg. A slight tendency to flexion was also present at the right elbow, in the fingers of the right hand, and at the right knee. This was not noticeable on the left side. While dictating notes upon the case, I observed a slight movement of flexion in the middle finger of the right hand, and a tremulous muscular wave in the corresponding metacarpal region. This was followed by a twisting or rotating motion of the forearm, from the position of supination towards that of pronaotin. These movements were repeated three times in the course of a few minutes; and then an exactly similar tremulous and spasmodic action was gone through with by the finger, hand, forearm, and arm on the left side. Still later the same took place on both sides simultaneously. The right great toe also twitched upward and downward at intervals of a few minutes.

Efforts were made to test for sensibility, but without result. He was totally unconscious of external impressions. Reflexes, however, were marked. The plantar reflex on the right side was good, and on the left it was decidedly exaggerated. Skin reflexes in the thighs, abdomen, chest, and arms were also examined for, and with the same result,—namely, the determination of good reflex response everywhere, and for the regions of the left half of the body not only good, but exaggerated. I did not examine for patellar reflexes, as I did not wish to move the patient any more than could be helped. The reflexes from the triceps brachialis of each side were marked.

Examination of the right radial pulse showed eighty-eight beats to the minute; of the left radial, ninety-two. The character of the pulse on the two sides differed markedly: on the right it was comparatively full and strong; on the left it was frequent, feeble, and irregular. The temperature taken in the right axilla was 99.1° F., in the left it was 99.2° F.

The respirations were forty-four to the minute when first counted. Noticing that at intervals he stopped breathing, with my resident physicians I carefully watched the process of respiration for more than half an hour. He would breathe with a little noise, but steadily, for from four to five minutes, and then, either with a long-drawn sigh, or with a struggling sound in the throat, he would cease breathing entirely, the period of complete suspension lasting from one-eighth to one-fourth of a minute. At the end of this period of apnœa, respiration would begin, at first feebly, but gradually becoming stronger. At the expiration of from four to five minutes the gap in breathing would recur. In this way his respiration continued, with alternations of breathing and apnœa. During the hiatus in respiration the pulse at the wrist became slower, fuller, and firmer. The heart-action was more labored. The face did not change in color or appearance, remaining pale and expressionless.

A drop of croton oil in castor oil was administered, the patient swallowing the dose with but little difficulty. Warming-pans were applied to his feet. He was ordered to be kept perfectly quiet, and milk in small quantities was directed to be given at intervals, if possible. A prescription containing potassium bromide and tincture of aconite was also ordered.

The stroke occurred at 11 A.M. He was

seen by me, and the above points noted, from 2 to 3 P.M. From 3 o'clock until he died, at 11.15 P.M., Drs. Allison and Gibb were in almost constant attendance upon him. The paralysis of limbs and face became absolutely general. The pupils became more dilated, and the face paler. The surface of the body was bathed in perspiration. The slight spasmodic movements in the upper extremities ceased during the afternoon. His urine, which dribbled from him, was removed by the catheter. Subsequent examination of it showed no albumen. No passage from the bowels took place. The heart-action and pulse became more rapid and feeble. At 6 P.M. the temperature taken in the right axilla was 100.8° F., in the left it was 101.2° F. The surface-temperature of the head at two points was carefully taken with a modified Seguin thermometer, at 7 P.M. The points selected for observation were one on the right side of the head, and the other on the left, about the middle of the "line of Rolando,"—that is, the line on the outside of the skull determined by measurements to correspond to the fissure of Rolando within. The patient being bald, the observations were more easily made and more likely to be accurate than if the hair had been in the way. The right Rolandic station gave a temperature of 102° F., the left only 98.5°. The axillary temperature was taken again at 10 P.M.: for the right axilla it was 101.2°, for the left it was 101°. The Cheyne-Stokes type of respiration continued until 9 P.M., when it gave place to rapid and shallow but interrupted breathing.

A post-mortem examination of the brain was made thirteen hours after death. On removing the skull-cap, a large quantity of blood poured out. The blood which escaped during the entire autopsy was collected, and amounted to fifteen fluidounces. Neither the skull nor the dura mater presented any abnormal appearances. The pia mater of the convex and median surfaces of the left hemisphere was intensely hyperæmic, except at its extreme anterior end. A large ecchymotic area more than two inches in diameter was present beneath the pia mater over the posterior extremities of the superior and inferior parietal convolutions and adjoining anterior margin of the occipital lobe. A deeper zone of congestion, with slight ecchymosis, was also to be seen at the middle Rolandic region. The pia mater of the convexity of the right hemisphere presented nothing unusual except marked hyperæmia over the lower two-thirds of the ascending convolutions and the anterior end of the inferior parietal lobule. Stripping the pia mater, numerous slight hemorrhagic extravasations were found in the fissures and sulci, particularly in those of the right side. During the process of removal of the brain from the skull, large quantities of blood poured from a rent in the end lobule of the right occipital lobe. Resting the brain on its convex surface, large masses of dark blood could be seen occupying the central region of the base from the pons to the optic chiasm; the blood enveloped the cranial nerves in this area, and infiltrated the membranes and the spaces beneath them far out into the Sylvian fissures. The cerebellum, pons, and medulla oblongata were next examined, leaving the ganglia and white matter of the hemispheres to the last. Over the superior vermiform process of the cerebellum was a thick mass of clotted blood. Hemorrhagic foci were found here and there in the pia of the cerebellar hemispheres, the substance of which showed a few bloody points. The fourth ventricle was filled and distended with dark blood; its floor showed a very slight depression or splitting at its upper part; the aqueduct of Sylvius was greatly dilated. The lateral ventricles, which were entered from below, were filled with blood; their cornua were also enormously distended with blood. The septum lucidum, fornix, corpus callosum, and commissures were broken down, and the lateral and third ventricles had become one cavity engorged with blood. The ganglia and tracts of the right side were closely examined without finding any hemorrhagic centre. The anterior extremity of the left optic thalamus and the cue-portion of the caudate nucleus were broken through. The hemorrhage had apparently taken place either from one of the lenticulo-optic or one of the posterior internal optic arteries. The middle portion of the internal capsule and adjoining region of the lenticular nucleus, as well as the districts of the optic thalamus and caudate nucleus, to which I have referred, had been disintegrated by the extension of the hemorrhage. I determined positively by vertico-transverse sections that the anterior regions of the striate bodies and capsules, and the posterior portions of the optic thalamus, capsules, and lenticular nucleus, were not destroyed. The hemorrhage had evidently spread rapidly in all directions from its primitive centre internally, breaking through with great force into the lateral ventricle. Numerous miliary aneurisms were found along the course of the striated and other arteries. No softening of the convolutions, or lesions other than those described, were discovered. The post-mortem examination was limited to the brain and skull.

Remarks.—The different stages of paralysis shown by the case are explicable in the light of the post-mortem examination. The marked right hemiplegia present at first was due to the effect of the primitive hemorrhage upon the ganglia and motor tracts of the left hemisphere. When the brain-substance was torn through and the ventricles became filled with blood, press-

ure was exerted upon the tracts of both sides, and general paralysis supervened. Until late in the history of the case, however, close examination, as might be expected, revealed a more decided paralysis on the right side.

According to Bastian ("Paralysis from Brain Disease," p. 232), "in cases of ventricular hemorrhage we very frequently meet with tonic spasms of one, two, or more limbs; or tonic may alternate with clonic spasms in the same parts. In other instances we have a condition of rigidity in the limbs of one side, combined with clonic spasms in one or both extremities of the opposite side." The only spasmodic phenomena presented by the case here recorded were the slight tendency to flexion at the right elbow and knee, and in the fingers, and the movements of flexion in the fingers and of rotation of the forearm and arm, and the twitching of the right great toe. Marked rigidity or contracture was absent. It may be worth while considering whether the ecchymoses beneath the pia mater in the motor regions of the cortex may not have been the cause of these peculiar movements.

The exaggerated reflexes on the side of the lesion, and the marked differences between the right and left radial pulse, were points worthy of note.

The axillary temperature, unfortunately, was not taken until two hours after the occurrence of unconsciousness, when it showed 99.1° F. for the right axilla, and 99.2° for the left; at 6 P.M. it was 100.8° for the right, and 101.2° for the left; at 10 P.M., 101.2° and 101°. Supposing an initial lowering of temperature to have taken place before the first observations were made, the case would come under the second group of Bourneville, of cases terminating fatally in from one to two days, in which the temperature is primarily lowered and afterwards heightened.

The observations on surface-temperature were remarkable because of the high temperatures obtained and the great difference between the two sides of the head. Broca, Brown-Séquard, Gray, and myself have found the temperature of the left side of the head to be usually greater than that of the right. Gray (*New York Medical Journal*, August, 1878) gives the following as normal average temperatures: Left side of the head, 93.83° F.; right side, 92.92°. The maximum normal temperature of the head is between 94° and 95°. Very striking, then, is the observation made in this case of a temperature of 102° for the right and of 98° for the left Rolandic station. I do not recall any observations on head-temperature in cases of cerebral hemorrhage.

The respiratory phenomena exhibited by this case were of great interest. Respiration after the stroke exhibited three stages: 1st. For a short time it was what has been called the "tobacco-smoker's respiration." 2d. It soon changed to the Cheyne-Stokes type, and continued of this character for several hours. 3d. Two hours before death the Cheyne-Stokes respiration ceased, and the breathing became regular, but constantly feebler and shallower. The breathing in the first of these stages is that which is not infrequently seen in cases of deep unconsciousness from apoplectic strokes or cerebral traumatisms. Observers are perhaps too much in the habit of describing the respiration in apoplexies simply as "stertorous." The peculiarities of respiration should be carefully studied in each case. I agree entirely with Nothnagel (Ziemssen's Cyclopædia, vol. xii. p. 102) that the noisy, snoring, "stertorous" respiration is not universally present in hemorrhagic apoplexy, and is, moreover, met with in sopor due to other causes. The respiration in the second stage was perhaps not in every particular of the usual Cheyne-Stokes type, but it was certainly a form of this respiration, which has been described by Laycock as "recurrent brief apnœa,"—an expression very applicable to this case. The period of nearly regular breathing was comparatively long, being from four to five *minutes*, the apnœal stage lasting from eight to fifteen seconds. Sometimes in the Cheyne-Stokes respiration the breathing will be interrupted several times in the same minute. The respirations presented the ascending character, beginning after the apnœa with feeble movements and progressively increasing until a certain plane was reached. The descending scale described as usually present was, however, absent, the respirations stopping abruptly. It was not a true "ascending and descending respiration." Traube (*Berl. Klin. Wochenschr.*, 1869, No. 27) first directed attention to Cheyne-Stokes respiration in cerebral hemorrhage. According to Traube (quoted by Rosenthal, "Clinical Treatise on Diseases of the Nervous System,"

vol. i. p. 159), this type of breathing is produced by an insufficient supply of arterial blood to the medulla oblongata. This lessens the irritability of the respiratory centre, so that the normal quantity of carbonic acid present does not suffice to provoke an inspiration. The long intervals in the respiration are to allow large quantities of carbonic acid to collect in the pulmonary and general circulation. Schiff (Foster's Physiology, American edition, p. 479) has observed Cheyne-Stokes respiration as the result of compression of the medulla oblongata. In this case, great and somewhat varying pressure was exerted by the blood in the fourth ventricle.

What is taught by this case in regard to the nature of the apoplectic shock or stroke? The view that apoplectic shock, as well as traumatic shock, is, sometimes at least, caused by sudden displacement of the cerebro spinal fluid, seems to be well borne out by the lesions found after death. The sudden and copious hemorrhage probably caused an instantaneous rush of the intraventricular cerebro-spinal fluid through the aqueduct of Sylvius into the fourth ventricle, upon the vital centres of the floor of which it acted in such a way as to cause the sudden arrest of the functions of the brain. This is the doctrine of Duret. The laceration in the ventricular floor, the ecchymoses beneath the pia mater at various points, the minute extravasations into the brain-substance, and the hyperæmia of the membranes, were lesions exactly similar to those found in cases of cerebral concussion.

I have seen the post-mortem specimens from another case of ventricular hemorrhage, although I had not the opportunity of studying the patient's condition during life. The appearances were in many respects the counterparts of those presented by the present case,—the partitions between the ventricle broken down, the cornua distended, the Sylvian aqueduct dilated and torn, etc. The condition of the pia mater and surface of the brain was, however, more remarkable than that exhibited by the case reported this evening. Both the pia mater and the cerebral substance were in the highest degree hyperæmic, the case affording me the most striking illustration of congestion of the brain and its membranes which I have ever seen. The vessels in many places seemed just ready to burst. Hemorrhages of considerable size had occurred in several places. A large clot having no connection with the ventricular hemorrhage was found on the outer surface of the medulla oblongata; another, also of large dimensions, was discovered in the right Sylvian fissure, just over the outer edge of the island of Reil. Other extravasations of blood, of less size, were found in the left fissure of Sylvius, and at various points on the cerebral and cerebellar surface. These hemorrhages all evidently occurred after the burst into the ventricles, and were probably the result of the displacement of the cerebro-spinal fluid and the disturbances of the circulation caused by the apoplectic shock.

1502 Columbia Avenue, Philadelphia.

THE PHYSIOLOGICAL ACTION OF ALCOHOL ON THE CIRCULATION.*

BY J. D. CASTILLO, M.D., U.S.N.

INCREDIBLE as it may seem, no thorough study of the action of alcohol on the circulation has yet been made, the only papers on the subject being those of Parkes and Wallowicz ("Experiments on the Effects of Alcohol on the Human Body"), Zimmerberg (quoted in Dr. H. C. Wood's Therapeutics, p. 119, 1879), and Dogiel (*Pflüger's Archiv*, 1874, Bd. viii.), which are far from being complete. The last two observers performed their experiments on animals, but furnish us results which are not only directly opposed to each other, but are entirely contradictory of what we know of the physiological action of alcohol from its clinical use. These facts would lead us to suppose that some fallacy underlies some of their experiments, and this suspicion becomes a fact when the results of the present elaborate investigation and the knowledge we have gained from its clinical use are compared with them. The advantages of considering *seriatim* the action on different portions of the circulatory system are patent, and I will, therefore, first consider the action on the pulse, and then that on the arterial pressure.

The pulse.—The pulse-rate, as well as the character of the pulse-curves, is very decidedly affected by alcohol, this action differing very materially whether the drug is given in small or in large intravenous doses.

* Abstract from Prize Inaugural Essay, University of Pennsylvania, March, 1880.

Small doses cause an increase of the pulse-rate with increased cardiac force, the pulse is full, strong, and regular, and the curves are higher, and the arterial pressure is increased above normal. The increase of the pulse-rate ranges from one-fourth to one-half of the normal. Thus, in a rabbit to which 10 m. dilute alcohol were given, the pulse was increased from 96 to 156 in one minute after intravenous injection; a minute and a half later it marked 164, and then gradually subsided. In a large dog to which 1 cc. absolute alcohol was given per jugular vein, the pulse arose from 112 to 180 in three minutes, and was full, regular, and strong. If these small doses are often repeated, the pulse becomes extremely rapid, feeble, and irregular, and is accompanied with a marked diminution of the arterial pressure. By continuing the administration the pulse continues increased, the pressure gradually falls, and suddenly the heart is arrested in diastole. At other times by repeated injections of small doses the pressure is lowered, the pulse-rate slowed, and the cardiac power is observed to fail gradually; finally, a last injection arrests the heart in diastole. It is to be noted that small doses cause an increase of the pulse-rate, with a strong, full, and regular pulse, and increased arterial tension; small doses, frequently repeated, cause an increased pulse-rate, with a pulse rapid, feeble, and irregular, and diminished arterial tension, indicating that the increase in the former instance is a stimulant action, and in the latter one of depression.

Larger doses cause an immediate fall of the pulse-rate, with irregular pulsations; the pulse-rate then returns to or goes above the normal, but is accompanied by diminished blood-pressure. The increase above normal may be equal to one-half of the normal. If while this increase exists another dose is given, the rate may be still further increased, but the arterial pressure is considerably diminished; or it may immediately sink, the heart in a few minutes being arrested in diastole. The diminished arterial tension accompanying the very marked increased pulse-rate, and the rapid, feeble, and irregular pulse-curves, show an interdependence of change from the normal, and indicate that the increased pulsations and diminished pressure are dependent not upon stimulation, but upon depression. Still larger doses cause the pulse-rate to become immediately greatly decreased, the blood-pressure to fall rapidly, and the heart to be soon arrested in diastole. Small doses, therefore, cause an increased pulse-rate, with strong, full, and regular pulse-curves, and increased arterial pressure; while large doses may cause an increased pulse-rate, with feeble and irregular pulse-curves, and diminished arterial tension, or a decreased pulse-rate, with diminished pressure, from very large doses.

Parkes and Wallowicz found in their very carefully conducted experiments that the pulse-rate was increased with increased force. Dogiel states that the pulse is first increased, then diminished, then increased again, and Zimmerberg, that the pulse-rate is decidedly reduced; but it must be borne in mind that the latter used alcohol in very excessive doses, being equal in man to doses of a quart or two: thus, the reason why he got such a decided reduction of the pulse-rate was because of the enormous doses he employed. Dogiel does not publish his experiments, and it is impossible to see where his error lies. The results of my own numerous experiments being uniform, and corresponding with the knowledge derived from the clinical use of alcohol, and with the results Parkes and Wallowicz furnish, seem to insure their correctness, and it remains now to investigate in what way or through what media alcohol effects these changes.

Dogiel asserts that the primary increase is due to a stimulation of the accelerator nerves, the diminution to a stimulation of the par vagum, and the final increase to a paralysis of the par vagum. Zimmerberg states that the diminution of the rate is due to a stimulation of the vagi centres. In my own experiments on animals with cut vagi nerves, seven in number, it was found that the changes in the pulse-rate were the same precisely as in normal animals, thus showing that these changes are wholly independent of any action on the peripheral vagi nerves. Next, three experiments were made on animals with cut cervical cords, artificial respiration being maintained, and it was found that no change from the above results occurred, thus excluding the vagi centres. In other animals the accelerator nerves were cut, with the same results, showing that neither the par vagum nor the accelerator nerves were affected. This certainly indicates that all these changes in the pulse-rate occurring in normal animals must

be effected by an action on the heart alone. In order more fully to prove this, a number of animals, with both the vagi nerves and cervical spinal cords cut, were experimented upon, and the results were the same. It may, therefore, be considered proven that the increase of the pulse-rate, with full, strong, and regular pulse-curves, and increased arterial tension, is due to a direct stimulation of the heart; and that the increased pulse-rate, with rapid, feeble, and irregular pulse-curves, and diminished arterial tension, and also the diminished pulse-rate, are due to a depression of the heart.

Blood-pressure.—Alcohol in small doses has no effect, or else causes an increase of pressure, while large doses cause a decrease. Dogiel asserts that the pressure is primarily increased and secondarily diminished, and that during the latter condition the vaso-motor centres are paralyzed. Zimmerberg with his excessive doses always got a decided fall, which he attributed to the heart. In my own experiments I attribute both the increase and the decrease to a direct cardiac action, since it has been found that after the isolation of the heart from any centric nervous influence the same changes in pressure still occur, and as I found that when the fall of pressure was very pronounced the vaso-motor centres and peripheries were still intact,—the vaso-motor centres responding normally when the sciatic nerve was stimulated, and the vaso-motor peripheries in the web of a frog's foot, under a microscope, remaining unchanged after the hypodermic injection. If alcohol is directly applied to the web, a contraction occurs; but this is undoubtedly due to a direct irritant action.

It may, therefore, be concluded from the uniform results of my fifty-odd experiments—

1st. That alcohol in small doses causes an acceleration of the pulse, with increased cardiac force.

2d. That this acceleration of the pulse and the increase of the cardiac force are due to a direct stimulation of the heart.

3d. That alcohol in larger doses causes an acceleration of the pulse, with diminished cardiac force, and that this is due to a direct depression of the heart.

4th. That if the dose be excessive the pulse-rate is diminished from the first, or the heart may be immediately arrested, being due to a direct paralysis of the heart.

5th. That the heart is always arrested in diastole.

6th. That small doses cause a rise of the arterial pressure.

7th. That large doses cause a fall of the arterial pressure.

8th. That these changes effected in the arterial pressure are due to the action of alcohol on the heart alone, in the former case being one of stimulation, and in the latter one of depression.

9th. That alcohol in small doses is a cardiac stimulant, and in large doses a cardiac depressant.

PHYSIOLOGICAL LABORATORY, UNIV. OF PENNSYLVANIA.

PRELIMINARY NOTE ON POISONOUS DYE-STUFFS.

Read before the Philadelphia County Medical Society, September 22, 1880,

BY HENRY LEFFMANN, M.D.

GENTLEMEN,—I present this evening a brief notice of some observations upon the topic of poisonous dye-stuffs, my object being mainly to inform the members that I am engaged in studying the subject, and invite assistance in so far as to be allowed opportunity of making chemical examinations in cases which appear to arise from poisons of this class.

It will not be necessary to explain to what effects I refer. Irritation and inflammation of the skin are the most common forms in which the poisonous action of dyed fabrics is supposed to show itself. A case of skin disease limited to a part of the body which has been in contact with a highly-colored article—shirt or stockings, for instance—is at once ascribed to the dye-stuff, and, as a rule, to some metallic poison contained in it.

Without occupying time in the discussion as to what metals may cause the trouble, I shall here limit myself to the one which is most commonly charged as the cause,—arsenic. This substance is widely distributed, is found in many common chemicals, and may thus easily find its way into dyes. Of late years an additional liability to its presence has arisen from the fact that certain organic dyes are manufactured by the use of arsenic acid and a portion of the poison remains in the dye.

The preliminary investigation has been directed to discovering how far the arsenic

which is in these dyes may find its way into the fabric. Experiments made upon aniline red, as sold to dyers, showed that some samples did not contain arsenic. Yarns dyed with samples that did contain arsenic were examined by delicate tests, and did not show indications of arsenic. Samples of the liquid, both before and after the immersion of the yarn, were examined, the result indicating that very little if any of the arsenic was removed by the fabric. I submit herewith a sample of cotton yarn dyed with an arsenical aniline in the proportion of ten ounces of color to one hundred pounds of yarn. Portions of this yarn, being tested, showed no indication of arsenic.

An interesting case occurred some months ago in Syracuse, New York. A woman purchased at one of the carpet-stores in that city a number of yards of carpet, and proceeded to make it up. She was soon attacked by some skin trouble, which she ascribed to the carpet, and she complained to that effect to the dealers. They at once stopped the sale of the goods, wrote to the wholesale house in New York City from which they purchased the goods, and this house at once sent the complaint to the carpet-works in this city. A sample of the carpet was submitted to me. I made careful tests for arsenic, and found none. I submit the sample and give a list of the various dyes used in it. Those in italics are most likely to contain arsenic.

Cotton warp: white, starch size; green, Prussian blue, flavine, turmeric, *sulph. indigo*, alum; orange, flavine, hypernic, *tin solution*. Woollen woof: white, bleached and tinted with *sulph. indigo;* green, picric acid, *sulph. indigo*, alum, Glauber's salt, *oil of vitriol;* orange, flavine, cochineal, *tin solution;* ruby, *magenta*, turmeric, Glauber's salt, *oil of vitriol.*

I hold that the explanation of many cases ascribed to these dye-stuffs is either coincidence or idiosyncrasy; and I shall be obliged to the members of the Society for any opportunities which may be afforded me for making further investigations in the matter.

THE first Boylston prize question for 1882 is a premium of three hundred dollars for the best dissertation on sewer-gas and its physiological effects on animals and plants. It is an experimental inquiry.

A NEW MYDRIATIC—ADDITIONAL NOTE.

BY H. S. SCHELL, M.D.

THE appearance of an article under the above caption, in the *Times* for October 9, has naturally aroused the inquiry, "What is it?" In response, I would say that homatropin is a derivative of atropin, and is so named because of the similarity of its properties to those of the latter drug.

Homatropin was discovered by Professor A. Ladenburg, of Kiel, in the course of some experiments upon the synthesis of atropin. He has so far succeeded in this purpose as to be able to recombine the primary products of the decomposition of the natural alkaloid. By the action of baryta and hydrochloric acid atropia is split into *tropin* and *tropic acid*, as follows:

$C_{17}H_{23}NO_3 + H_2O = C_8H_{15}NO + C_9H_{10}O_3$.
Atropia + water = tropine + tropic acid.

In the course of investigations as to the possibility of making tropine and tropic acid artificially, he discovered that the former, under the action of strong hydrochloric acid and other conditions, is converted into a new base, which he calls *tropidine* = $C_8H_{13}N$. It is of an oily consistency, and has no effect on the pupil.

A number of new bases, called *tropeïnes*, have been obtained by warming tropine with organic acids and diluted hydrochloric acid. The only one of these which seems to possess special interest is homatropin, or *oxytoluyl tropeïne*. It is prepared from tropine, amygdalic and dilute hydrochloric acids. Merck states that it crystallizes in transparent, colorless, regular crystals. These are hygroscopic, and, at the same time, do not readily dissolve in water.

The *hydrobromate*, on the contrary, forms a salt which is not hygroscopic, but which is soluble in ten parts of water, and the solution keeps well. Merck, of Darmstadt, has undertaken the manufacture of homatropin hydrobromate on a large scale. It will, no doubt, be extensively used as its properties become widely known. I find it convenient to rely upon it exclusively in refraction cases in my consulting-rooms.

THYMOL.—Thymol-vaseline ointment is made by dissolving twenty grains of thymol in an ounce of vaseline. It is useful in eczema and as a parasiticide.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

CLINICAL SERVICE OF DR. HORATIO C. WOOD.

Reported by C. H. WILLITS, M.D.

CASE OF CLOT BELIEVED TO BE IN CRUS CEREBRI, FOLLOWED BY HEMIPLEGIA AND BY LOSS OF SENSIBILITY AND OF SPECIAL SENSES. ALSO, CEREBELLAR TUMOR WITH AFFECTION OF SPECIAL SENSE.

I WANT to call your attention to-day, gentlemen, to a case of brain-disease which is very interesting from a diagnostic point of view, but which, unfortunately, is not so interesting to the patient in reference to a cure.

This man, B——, aged 67, a sailor by occupation, presents the following brief history: eighteen years ago he fell from the mast-head of a ship, from the effects of which fall he remained unconscious for sixteen days, and when he awoke was paralytic, with the symptoms still persistent.

Now, you will notice that the patient is a powerfully-built man, with good muscular development, but, as he walks or stands, seems to have no control over the right side, and in walking uses his right leg in the manner of a walking-stick, the muscles being perfectly rigid and all motion being seated in the pelvis, the side of which is elevated at each step. You will notice also that the right arm and hand are paralyzed, the index-finger only retaining some slight motion; and if you will pay particular attention while I ask him a question, you will be impressed by his particular intonation when he speaks. There is no aphonia, because no loss of voice, and no loss of speech, therefore no aphasia; but he has, more correctly speaking, aphamia, or loss of the power of articulation, due to paralysis of the muscles of the face.

It is, therefore, a case of right-sided hemiplegia. There is nothing remarkable in that; but when I stick a pin into his arm he does not feel it, or if I make a pincushion of his leg, the pin can penetrate any depth without any apparent pain.

Again, if I put this burning match against his leg, he is not conscious of it until it has been in contact a long time; nor does he recognize the presence of ice.

Along with this loss of sensibility there is almost total blindness of the right eye, he not being able to see my fingers placed close to the eye, and the pin brought in contact with it shows entire loss of conscious sensibility, although the reflex movements are retained.

When my watch is placed close to the ear he cannot hear it, and when I place some salt in contact with his tongue there is no apparent sense of taste.

We have, then, the history of a blow on the head, from which resulted right-sided hemiplegia and loss of general sensibility which comes up close to the median line of the body without crossing to the opposite side, and complete loss of the special senses, these symptoms all having come on suddenly, not gradually.

Now, what is the matter with the man?

There is little doubt that this man has a clot, resulting from the blow, somewhere in the brain, and that this clot must be situated in the brain proper, and not in the pons or medulla oblongata.

For physiological purposes the brain is divided into two parts, the lower brain, or mesocephalon, and the higher brain, or cerebral centres. In this case the clot cannot be situated in the mesocephalon, because the influence is far too wide-spread.

Most of you know that there are two kinds of action, conscious and unconscious, or voluntary and involuntary, and that it is not necessary for action that we perceive an impulse, for it is a common thing for us to move unconsciously in either anger or sleep. When an impulse is transmitted along a sensory nerve it is received at the receptive centre of the medulla, and if, either from its own feebleness or owing to some obstruction to its farther progress onward, it does not reach the higher brain-centres, it may be reflected across to a motor fibre, and a motor impulse, which is purely involuntary or reflex in its character, result. But, on the contrary, to have a voluntary action, it is necessary that the track to the brain proper be open, and that there be sufficient impulse to rouse the brain to perceive the impression which is registered upon the medulla.

When I stick the pin in this man's eye, although sensation and sight are lost, yet he winks, which is a proof that there must be damage to this man's higher centres which precludes him from perceiving the sensation, while the centres of the trigeminal nerve are preserved. Further, if the clot was in the mesocephalon, it would affect some one and not all of the centres of special sense.

Now, where is this clot situated?

You know that above the pons are two white bands of nerve-fibres, the crura cerebri, which are the conductive means from the lower to the higher brain. Soon after their divergence each crus contains within it a small mass, called the locus niger, which separates it into the anterior and posterior portions. Farther on in its onward course it passes through two masses of ganglionic tissue, the optic thalamus and the corpus striatum.

Autopsies have shown that the formation of a clot involving the posterior portion of the crus below the optic thalamus is always followed by the symptoms of hemianæsthesia, such as are present in the case before us, as the fibres which pass from the mesocephalon to the cortical centres of conscious perception travel along this part of the crus.

It is a matter of scientific interest to know where these fibres go and where these cerebral centres are; but the almost complete impossibility of tracing these minute and numerous anatomical structures makes us accept the results of all such endeavors with reserve.

Meynert claimed to have traced them into the occipital lobes. Ferrier has found much reason for believing that the perceptive centres in the monkey are situated in the occipital lobe. In man, however, this is rendered doubtful by the fact that we may have complete loss of the entire lobe with loss of sensibility.

I saw, however, a case last March which seemed in a measure to sustain the views of Prof. Meynert. The following is an abstract from my case-book. A woman, aged 54, who had usually enjoyed good health, was taken with the general symptoms of Bright's disease, confirmed by examination of the urine, together with a peculiar paroxysmal headache confined to the anterior part of the head, marked difficulty of finding words, and failure of memory.

There was also some slight drawing of the face to one side and slight paresis of the left arm. From this time forward the symptoms grew steadily worse, the loss of memory becoming very prominent, and the aphasia increasing until nearly complete.

The palsy of the right side varied much from week to week, gradually increasing, but never becoming total.

Between two and three weeks before death the sense of smell and taste disappeared, and there was marked mental failure and apathy, but the patient knew everybody, and the sense of sight remained, seemingly, good.

The loss of the senses of smell and taste distinctly preceded by a considerable interval the coming on of stupor: how far the loss of taste was dependent upon the loss of smell was not distinctly made out, owing to the aphasia and lack of intelligence.

At the autopsy the kidneys and spleen were in an advanced state of atrophy, the brain, external surface and membranes, seemingly normal, except in the left island of Reil, where it was much softened, with microscopic evidence of an old clot in it. In the right hemisphere, in the posterior lobe a gliomatous tumor was found the size of a pigeon's egg, which caused great bulging into the ventricle, and the whole lobe, in the interior, was in an advanced stage of yellow softening, with frequent small hemorrhages.

I remember also a case which occurred many years ago in the wards of this house, in which, after death, the whole posterior cerebral lobe was destroyed by an abscess, and in which, during life, no loss of sensation or of the special senses was detected. I suspect, however, that in this case, and in very many of the reported cases of occipital disease, loss of sense was not perceived because it was not properly looked for. Coming back to the case now before us, the completion of the sensory palsy shows that the clot is not a cortical one, and we must conclude that it is situated in the crus and has been sufficient to destroy both the anterior and the posterior portion of the peduncle.

Let me say, before dismissing the case, that, as we properly understand the term, hemiplegia is a paralysis of the arm and leg of the same side, but not of the muscles of the trunk.

If you will notice this man, you will see that he breathes freely and can use voluntarily the muscles of respiration.

The following reason for this want of paralysis of the trunk-muscles in hemiplegic cases has been brought forward by Broadbent, of England. The legs are accustomed to act independently of each other, as are the arms, but not so with the muscles of respiration; they are used to action together. These centres, which are connected by commissural fibres, are so

accustomed to responding in union that the impulse is sent across and onward, although one centre is really gone.

This theory seems to be supported by these cases, and by the fact that independently-acting muscles become more readily paralyzed than those accustomed to act in unison.

As regards the treatment in this case, of course nothing can be done, the condition being not a disease, but a result.

TRANSLATIONS.

Treatment of Tinea at the Saint-Mandrier Hospital at Toulon.—The Saint-Mandrier Hospital, one of the largest French hospitals, is situated at Toulon, and is under the charge of a well-known physician, Dr. Bérenger-Féraud, who has taken advantage of his opportunities to collect the statistics of tinea as treated in this institution, and publishes the results in the *Bulletin Général de Thérapeutique*, vol. ii., 1880, p. 49.

From 1860 to 1879—that is, in the space of twenty years—five hundred and ninety-three cases of tinea were treated in this hospital, the total number increasing year by year, and the proportion of cases as compared with the total number of cases of every description under treatment also increasing, the latter from .03 to 2.60 per cent. This increase is accounted for, according to Dr. Féraud, by the large number of sailors and others coming from Cochin China, and the increase in consumption of Algerian beef.

Dr. Féraud gives a table of some ten substances employed in the treatment of tinea, with the results obtained in the case of each. Among the substances used with little or no success were calomel, garlic, male fern, ethereal oil, pepo, and eucalyptus. Pomegranate in various forms was employed with varying success. The leaves, fruits, the herbaceous stems, and extract of the cortex were not successful, while the dry stems were more active, curing twenty-five out of thirty-nine cases. The various derivatives of pomegranate, punicene, sulphates of pelletiérine and isopelletiérine, and the tannates of methylpelletiérine and pseudopelletiérine were tried without much success in a number of cases. The most successful of all the remedies used, however, was the tannate of pelletiérine, which cured sixty-one cases out of eighty. Excluding a number of these substances which were simply used experimentally, the total proportion of cases successfully treated was 29 per cent., —a figure which seems small until it is mentioned that no case was considered successfully treated unless the head of the worm came away and was distinctly recognized.

Dr. Féraud has a poor opinion of the *pepo maxima*, which is, as is known, the most popular domestic remedy, and one largely used by the profession. After the most thorough and careful use of this remedy he succeeded in bringing away the head in only 7 or 8 per cent. of the cases.

Treatment of Chronic Ulcers of the Leg.—Courty (*Cbl. f. Chir.*; from *Jour. de Thérap.*, 1880, No. 11) has recently made an addition to the abundant but not fruitful literature of this subject, in which he begins by examining the question, What is the cause of the proverbial stubbornness of these ulcers? Apart from various disease-diatheses, from injuries to the tissues, and the influence of the vertical position, the chief trouble is local. The principal points in treatment are: 1, to excite the formation of healthy granulations; 2, to cause absorption of the swollen and hypertrophied tissues; 3, to prevent too rapid desiccation of the superficial epidermic layers during the process of cicatrization. To attain the first of these objects the author uses alternately rest, and active and passive movements. By rubbing and massage the circulation is aided. By wrapping the limb in cotton, plaster, rubber, etc., an antiseptic atmosphere is gained, and also methodical compression. By means of stimulants, as arsenic, copper, red oxide of mercury, the formation of granulations is favored. By nitrate of silver, aromatics, balsams, opium, etc., rapid cicatrization is effected.

Courty's procedure in leg-ulcers is as follows. First the sore is cleansed by washing with antiseptic solutions, as carbolic acid, salicylate of sodium, thymol, chloral, permanganate of potassium. Then, later, soap or an alkali is used to remove the débris and excess of epidermis. Proceeding then to the stimulation of the granulations, Courty spreads red precipitate ointment (strength of 1–50 to 30) on fenestrated pieces of linen, and then lays

these evenly over the ulcer. Over this cotton compresses are laid in sufficient thickness to absorb all purulent discharge. Over this is placed a slightly compressive rubber bandage. Courty says that patients soon learn to put this bandage on for themselves twice daily, which is advisable. He thinks that the red precipitate ointment, combined with the warmth and moisture, lead to active hyperæmia of the granulations, with absorption of the callous edges of the ulcer. When the granulations begin to grow excessive, and the border of the ulcer has softened down, it is time to begin the attempt at solid cicatrization. Courty thinks that care should be taken at this stage to avoid too rapid drying of the newly-formed epidermic layers, and the consequent puckering or fissuring about the border. Moist warmth he thinks best effects this.

Among the means used to favor cicatrization, Courty recommends an aromatic wine, containing occasionally some salt of copper or arsenic. Transplantation also, according to Courty, is advantageous when there is an extensive granulating surface. When the aromatic wine cannot be employed, nitrate of silver may be used, or, if this is too strong, Sydenham's laudanum. Frequently the application of the aromatic wine is followed by dressing with an ointment containing one part tinct. opii to ten parts simple cerate. This opium ointment is almost invariably employed together with compresses to finish up the cicatrization.

ANTISEPTIC PREPARATIONS. — M. J. Lucas Championnière gives the following formulæ (*Jour. des Sci. Méd. de Louvain*, 1880, p. 345):

Aqueous Solutions of Carbolic Acid.—For hospital use it is a good plan to color the stronger solutions red, so that attendants shall not mistake one for another.

	Stronger solution.	Weaker solution.
℞ Crystallized carbolic acid,	ʒxiij;	ʒviiss.
Alcohol,	ʒxiij;	ʒviiss.
Water,	Oij;	Oj.

Carbolized Oil and Glycerin.—

No. 1.—For oiling catheters, speculums, etc.:

℞ Crystallized carbolic acid, ℈iv;
Olive oil, ʒijss.

No. 2.—For dressings:

℞ Crystallized carbolic acid, ℈viij;
Olive oil, ʒijss.

Chloride of Zinc.—The most convenient solution for disinfecting purposes is one of eight parts to the hundred of water. This solution is strongly caustic, and leaves a white pellicle on any wounds which it may touch, with a thin cicatrix, which does not prevent primitive reunion. This solution is called for in wounds which have been or must necessarily be exposed. It is also to be recommended in certain cases of cold abscess where the cavity is organized. It is especially useful, however, in cases where carbolic acid poisoning is to be feared. The solution should then be of the strength of one to two to the hundred, or weaker.

Catgut.—Carbolized catgut is usually so poorly prepared by manufacturers that the surgeon should make his own. To have a ligature at once solid, distinctly antiseptic, and sufficiently resistant, the following formula should be exactly followed:

℞ Crystallized carbolic acid, ʒv;
Water, ʒss;
Olive oil, ʒijss.

The water is added to the carbolic acid so as to form a sort of emulsion, and this is dissolved in the oil with vigorous agitation. A few bits of stone should be placed in the bottom of the flask containing the solution, so as to prevent the catgut from lying on the bottom. The latter should be unbleached, and should be rolled into coils and placed in the flask, completely covered with the carbolized oil, and allowed to remain there for five or six months.

Silk Ligatures.—When catgut cannot be employed, silk ligatures, as recommended by Lister, may be used. These are prepared by plunging them into melted wax containing thirty grains of carbolic acid to four drachms of wax. The ligatures are then passed between a fold of linen to equalize the distribution of the wax and to remove the excess.

Boracic Acid and its Preparations.—Boracic acid is an excellent antiseptic, according to experimenters. In practice, however, it has not been found so available. Its slight solubility is a drawback to its use. However, it has the advantage of being non-poisonous, and may be used in certain localities when the other antiseptics cannot be employed. A saturated solution in the cold contains four parts to the hundred of water. As boiling water takes up one-third of its weight, advantage is taken of this to make boracic lint by dipping absorbent cotton in the solution.

The fine crystals which cover the texture of the cotton are not sharp, and are unirritating.

Pleuritic Effusion — Treatment by Hypodermic Injections of Pilocarpin. —Dr. Haminio Tassi (*Jour. des Sci. Méd.*; from the Italian) found, in a case of pleuritic effusion on the left side, that the greatest relief was given by injections of pilocarpin in the dose of one-third to one-half grain daily, which were well borne. The following symptoms were observed. The pulse increased in frequency a little after the injection, and continued thus for a short time. The temperature likewise increased within about six minutes, continuing so for some twenty minutes. At this time perspiration was established, after which the temperature gradually diminished to a degree somewhat lower than before the injection. Sialorrhœa showed itself a few minutes after the injection, and lasted several hours. There was no hiccough, nor any vomiting; but secretion of tears preceded perspiration, and sometimes lasted about an hour, and was confined to the right eye. Pupillary atresia was observed in only a single case; there was always dilatation; urine was scanty.

Generalized Eruption after the Use of Carbolic Acid Dressings.—H. Zeissl (*Cbl. f. Chir.*, 1880, p. 542; from *Wien. Med. Wochenschr.*) reports a case of erythema urticatum following the employment of Lister's bandage in complicated fracture of the leg, and appearing on the eleventh day of its application. The dermatitis localized itself upon the back, sides, and extremities, displaying a diffuse patchy redness, strewn with isolated urticarious quaddels. The urine was dark green. The eruption faded away when salicylic acid was substituted for carbolic acid.

Inflammatory Disease of the Skin caused by a hitherto undescribed Acarus.—Geber describes an inflammatory skin disease occurring in laborers handling barley. A few minutes after coming in contact with the parasite a sensation of burning and itching is experienced, which is evidently due to the irritating influence of a yellowish-brown powder found on the hands. On microscopic examination, this powder is found to consist almost entirely of living and dead animals. On strewing the powder on the skin of healthy individuals, after a short time urticaria is produced. In more delicate skins, and after longer contact, papules, vesicles, and pustules, with the symptoms of eczema, are produced. Frequently loss of appetite, sleeplessness, and febrile symptoms occur, running over four to six days. In extreme cases more or less generalized dermatitis, with constitutional symptoms, occurs. The parasites are of an oblong-oval shape, yellowish-white color, and .022 centimetre long. They have a round head, with four pairs of feet. They belong to the Acarinæ. Since neither ova, embryos, nor sexually-different animals were observed, Geber thinks the parasite as found on barley occupies an intermediate stage of existence. He thinks the parasite similar to that found on corn and named by Ch. Robin *Chritoptes monunguiculosus*. He believes it to be a commoner cause of inflammation of the skin than is generally supposed.

Paternal Influence in Hereditary Syphilis.—A. Wolff (*Cbl. f. Chir.*, 1880, No. 32), as the result of the study of seventeen personal and twenty-eight other cases, concludes as follows. In every case in which the mother is affected, the child is syphilitic or there occurs abortion. If the father is syphilitic and the mother remains healthy, the children are born healthy and remain so. Wolff denies the paternal infection entirely. He has never seen a child with hereditary syphilis whose mother has not shown more or less decided symptoms of the disease or has not at least given a history of infection.

Ricord's *choc en retour* and Von Bärensprung's infection in procreation lack foundation in facts, as also does the theory of late hereditary syphilis resulting from paternal infection, which is entirely unproved.

Double Fracture of the Inferior Maxilla — Treatment by the Elastic Bandage.—Thibierge (*Cbl. f. Chir.*, 1880, p. 591; from *Gaz. Méd. de Paris*), after replacing the broken bones, fastened them in place by an elastic bandage. A cure was obtained, without necrosis or deformity, in a month.

Alkalies in the Treatment of Sterility.—Professor Pajot, in a note to the *Bull. Gén. de Thérap.* (vol. i., 1880, p. 543), alludes to the statement made in a former number of that journal regarding the influence exercised by an acid condition of the vaginal secretions in preventing conception, and says he has used injections of Vichy water for many years in these cases.

LEADING ARTICLES.

THE PRODUCTION OF DIPHTHERIA IN THE LOWER ANIMALS.

DRS. H. C. WOOD and H. F. Formad have made a report to the National Board of a research made upon this subject. It is well known that pseudo-membranous affections occur in the lower animals offering symptoms similar to those of diphtheria in man, but it is not certain that these pseudo-membranous affections in the lower animals are the same as the human disorder.

Drs. Wood and Formad first attempted to create such affections by inoculating animals with membrane taken from persons sick with diphtheria. The poison was put in little pockets made with a lancet under the skin, or inoculated by scarification in the mucous membrane of the mouth: in many instances both methods were simultaneously practised. Thirty-two experiments were made, with six deaths. In no case was anything like diphtheria caused, except that in one experiment there was an indication of exudation upon the trachea, which, whilst it may have been due simply to a catarrhal inflammation, presents some of the characteristics of false membrane.

It has been asserted by Oertel that animals which have been inoculated with diphtheritic material die with their internal organs infested with micrococci, and that the presence of these is characteristic of diphtheria. Drs. Wood and Formad examined the internal organs of the rabbits which died, as well as the blood of those which survived, and found no micrococci, in this agreeing with Curtis and Satterthwaite.

In the post-mortem examinations in every case the internal organs were tubercular, and in many cases intensely so; tubercular disease was also found in the organs of rabbits which were killed some days after inoculation. It is therefore a very natural belief that in those cases in which death was long delayed it was due to tuberculosis. It certainly is very possible that when death takes place soon after inoculation it may be the result of a non-specific blood-poisoning, and not of diphtheria. In the experiments of Curtis and Satterthwaite death not rarely occurred in a very brief time; in those of Drs. Wood and Formad it was almost always very long delayed. The difference may have been from their using smaller portions of the diphtheritic material and inoculating less deeply than did the New York savants. In no case did inoculation in the mouth produce either local or general symptoms.

In order to discover whether the diphtheritic exudation acted specifically in the production of tubercle, or whether it merely set up a local inflammation which formed a focus of infection, small masses of innocuous foreign matters were placed under the skin. In five out of nine of these experiments tubercle was found after death. This large proportion apparently demonstrates that a simple local inflammation may, in the rabbit, act as a source of tubercular infection. When diphtheritic matter was inoculated, inflammation was almost always induced at the seat of the lesion, with the formation of large lumps containing cheesy matter; so that Drs. Wood and Formad reasonably conclude that the tubercles were secondary to these inflammatory foci, and were therefore an indirect, and not a direct, result of the inoculation.

The method by which Trendelenburg asserts that he succeeded in producing diphtheria in rabbits consists in placing the exudation matter in the trachea. In four experiments our investigators obtained once Trendelenburg's results; in numerous instances they proved that ammonia is able to produce in the cat and dog, as well as in the rabbit, a pseudo-membranous trachitis. Professor Oertel states that the membrane produced by cauterization of the trachea differs from diphtheritic membrane in containing no bacteria. In the recent research, when the death occurred very quickly, bacteria and micrococci were less abundant in the traumatic membrane than in that taken from the throat of patients, but when the animal survived some days, and the bacteria had sufficient time to develop themselves,—when, in other words, they were afforded as good oppor-

tunity of growth as in the natural disease,—they were immensely abundant, in some cases seeming to make up a large part of the bulk of the membrane.

If it be possible to produce a fatal pseudo-membranous trachitis by placing the diphtheritic membrane in the trachea, and possible to cause septicæmia by inoculating other portions of the body with the same material, it would appear as though diphtheria might be originally a local disease with a subsequent septic poisoning; and ten experiments were made to determine whether any products of disease other than diphtheritic exudations are capable of causing pseudo-membranous trachitis.

In two of these experiments pseudo-membranous trachitis was caused by the introduction of organic matter into the trachea. In both of the cases in which false membrane was produced the injected material was pus, and it will be noticed that only four such experiments were made; so that the proportion of successful results was very large,—much larger, indeed, than with true diphtheritic exudation.

Trendelenburg found that not only ammonia but also various other chemical irritants are capable of causing the formation of false membrane in the trachea; many years since it was proven that tincture of cantharides will do the same thing. It would seem, therefore, that in the trachea the formation of a pseudo-membrane is not the result of any peculiar or specific process, but simply of an intense inflammation,—an inflammation which may be produced by any irritant of sufficient power. This fact, certainly, is very suggestive in regard to the pathology of diphtheria.

It is certain that, as in the lower animals, so also in man, chemical irritants will produce a pseudo-membranous trachitis; we are also well assured that there is no anatomical difference which can be detected with the microscope between the lesions of true croup and of diphtheritic angina. A difference has been believed by some pathologists to exist between the two diseases, in that in croup the membrane separates easily, in diphtheria with great difficulty, from the mucous membrane. This seems to arise from a misunderstanding. The mucous membrane of the fauces and mouth has a squamous, not easily-detached epithelium, and consequently membrane connected with or springing from such surface is firmly adherent. The epithelium of the trachea is columnar, ciliated, and detaches with the utmost facility even in the normal condition of the organ; hence membrane attached to it separates readily. The membrane of diphtheritic trachitis is always readily detached in the line of the epithelium. The preparations of Drs. Wood and Formad show that the exudation of the croupous inflammation excited artificially in the trachea is not merely superficial, but also extends below the basement membrane. Some of the best clinical authorities of the day teach that there is no essential clinical difference between true croup and diphtheria, cases commencing apparently as local sthenic inflammation and ending as the typical adynamic systemic poisoning. Every practitioner must have seen cases of angina in which he was in doubt whether to call the affection diphtheria or not: the very frequent diagnosis of "diphtheritic sore-throat" is a strong evidence of this. There have been cases in which diphtheritic matters absorbed by a wound have produced symptoms very closely resembling those of ordinary septic blood-poisoning from post-mortem wounds, etc.; there have been cases of the formation of false membrane about wounds, etc., without any known exposure to a specific diphtheritic poisoning, indicating that the systemic tendency to this peculiar form of exudation is capable of being engendered by other than the specific poison of diphtheria; finally, diphtheria seems sometimes to be produced by exposure to cold.

A general view of these facts seems to indicate that the contagious material of diphtheria is really of the nature of a septic poison, which is also locally very irritant to the mucous membrane; so that when brought in contact with the mucous membrane of the mouth and nose it produces an intense inflammation without absorption—*i.e.*, by a local action. Whilst absorption is not necessary for the production of the angina, it is very possible that the poison may act locally after absorption by being carried in the blood to the mucous membrane. Further, under this theory it is possible that the poison of diphtheria may cause an angina which shall remain a purely local disorder, no absorption occurring; or a simply local trachitis produced by exposure to cold, or some other non-specific cause, may produce the septic mate-

rial whose absorption shall cause blood-poisoning, the case ending as one of adynamic diphtheria.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held at the Hall of the College of Physicians, Philadelphia, September 22, 1880, Dr. Albert H. Smith, President of the Society, in the chair, when Dr. H. Leffmann read a paper entitled "A Preliminary Note upon Poisonous Dye-Stuffs" (see page 46), which received a vote of thanks.

CRUSH OF NASAL BONES, WITH EXPEDIENT FOR OBVIATING DEFORMITY.

Dr. Charles B. Nancrede reported a case of compound comminuted fracture of the nasal bones and nasal process of the superior maxillary bones caused by the kick of a mule, in which he had resorted to the expedient first suggested by Erskine Mason, of New York, for the purpose of supporting the bridge of the nose until union took place. The accident occurred about seven weeks ago to a patient admitted into the Episcopal Hospital of this city. Finding the parts crushed and shapeless, he had passed an acupressure-pin across through the root of the nose, and held the bones in position with adhesive plaster, with cold-water applications. No grave complications presented themselves, and in the course of a week he removed the pin, and was much gratified to find a good result, which he was certain could not have been obtained by any other means, for the articulating process of the frontal was fractured, and probably the perpendicular plate of the ethmoid as well.

CEREBRAL APOPLEXY.

Dr. Charles K. Mills reported a case of cerebral hemorrhage into the basal ganglia (see page 41).

Dr. C. B. Nancrede inquired if the lecturer laid any stress, in the diagnosis, upon the flexion of the middle finger of the patient's hand.

Dr. Mills said that he had observed this point particularly because it might be of service in localizing a lesion of the cerebral cortex. According to the observations of Fritsch and Hitzig, and those of Ferrier, the centre for the right upper extremity is located behind the fissure of Rolando, in the fourth and fifth descending parietal convolutions. Irritation of this point, in the investigations of Ferrier, caused flexion of the fingers. In the case reported, the blood was exuded just below this region. He did not say that this was the explanation, for pressure upon the basal ganglia might have caused it. If this symptom, however, had remained isolated, he would have believed that it pointed to a cortical lesion.

Dr. Nancrede said that the local contraction must have been caused by the action of the interossei muscles, which extend the first phalanx and flex the second and third. He also asked if such a large effusion was not unusual, and whether or not the convolutions showed unusual pressure.

Dr. Mills said that the ventricles were enormously dilated, and the entire brain pressed upward; the convolutions were flattened; the vessels were much congested, and during the examination seventeen ounces of blood escaped. He had seen only one other case in which the hemorrhage had proved as extensive. The vessels also showed evidence of miliary aneurism, and one specimen taken from the base showed a rupture of its coats; there were also small spots of dilatation and points of degeneration. In regard to the muscular contractions in the fingers, as they existed on both sides, they were probably of central origin.

Dr. Packard asked whether hemorrhages upon the surface of the brain would cause a local rise in the temperature.

Dr. Mills replied that he had not taken any surface-temperature observations in this case; but in other cases he had undoubtedly found a rise under similar circumstances, and believed that this might be of service in localizing the clot.

CASE OF FOREIGN BODY IN THE URETHRA AND BLADDER REQUIRING PERINEAL SECTION.

Dr. Charles B. Nancrede reported a case of unusual interest, occurring in the wards of the Episcopal Hospital, of a patient who was admitted with a supposed medical ailment. On the second day after admission the speaker's attention was called to the case. He found him passing very little urine. Upon examination, an ordinary pen-holder was found lying in the urethra, partly in the bladder and partly in the spongy urethra, the end being discernible to the touch in the perineum. The size was about No. 25 French scale. It was found to be impracticable to withdraw the foreign body by the ordinary forceps through the meatus, and perineal section was resorted to. With the exception of some cystitis, the man did well after the operation; no fistula resulted. The section was made in the median line, through the bulbous portion of the urethra. No severe hemorrhage occurred.

Dr. Schapringer suggested the introduction of a large catheter to envelop the foreign body.

Dr. Packard said that a mechanical difficulty existed to prevent the plan just pro-

posed. The difficulty was in the long, straight extremity of the pen-holder; the force of the friction of the catheter would not be sufficient to maintain its hold, even if it could be coaxed over it as suggested. He inquired whether it would not have been a simpler plan to perform the ordinary lateral lithotomy operation, and cut the stick in half and withdraw it in section.

Dr. Nancrede said that the operation performed had occurred to him as being the most appropriate. The hemorrhage was readily controlled by hot-water applications.

THE USE OF CHLORATE OF POTASSIUM IN FURUNCULAR AND CARBUNCULAR AFFECTIONS.

Dr. J. V. Shoemaker reported remarkable success from the use of chlorate of potassium, given in large doses, in scrofulous skin diseases and in furuncular and carbuncular affections. He had lately been invited to see a case in the practice of Dr. Boardman Reed at Atlantic City. It appeared that the use of large doses of this salt had decidedly reduced the amount of suppuration in the case named; and in other cases he had had equally satisfactory results.

Dr. Reed, being present, was invited by the President to give the details of the case.

Dr. Boardman Reed said that the patient was a young girl who had two carbuncles, one upon the back of the neck and the other in front of the ear; they afterwards extended downward until the affected area was about five inches in extent. The patient was very weak; she became feverish, and the pulse was rapid and feeble. Very little hopes of her recovery were entertained until the chlorate of potassium was used in decided doses (gr. iii every three hours), in conjunction with iron and supporting diet, when she rallied and subsequently became quite well.

Dr. Frank Woodbury said that he would regret very much if the impression were gathered from the case just mentioned, or from remarks that had been made before the Society, that potassium chlorate is an entirely harmless remedy, as it has caused death in a number of reported cases. The symptoms of poisoning are by gastro-intestinal irritation, and as small an amount as half an ounce has proved fatal. Like all the other potash salts, the chlorate possesses high diffusive power, and readily enters the blood, to which it gives a bright-red hue. This is not due, however, to its yielding any of its oxygen to the red-blood cells, because it is a very stable salt and requires a red heat before it is decomposed. It is eliminated in its own form, appearing in nearly all the secretions. Being only slightly soluble in water, it is deposited very frequently in the pelves of the kidneys; and in cases such as diphtheria, where the renal organs are already affected, or in chronic Bright's disease, such obstruction might prove of serious import in an already damaged kidney. The speaker, after listening to Dr. Drysdale's paper upon "Chlorate of Potassium in Croup," read before the Society about two years ago, had used it as recommended in comparatively large doses, and had seen several infants profoundly impressed by it, and even threatened with collapse, having a pallid face, a cool skin, feeble respiration, fluttering pulse, and complete muscular prostration, from which they recovered only after the withdrawal of the remedy and the application of heat and stimulants. Several articles had appeared in the medical journals lately, calling particular attention to this danger from chlorate of potassium. He wished to emphasize the fact that there is no evidence whatever that when given internally it yields any oxygen to the blood, as has been asserted; nor is it a stimulant to the circulation; on the contrary, it is capable of causing profound general depression, and is a paralyzer of the heart. In large doses it is a gastro-intestinal irritant, while after absorption the danger of blocking the kidneys mechanically with crystals of the salt, precipitated from concentrated urine, should not be forgotten.

Dr. Shoemaker said that Dr. Alexander Harkin, of Edinburgh, had reported a few years ago a number of cases of scrofula and tuberculosis in which this remedy had produced excellent results. He had himself been using it for four or five years, and had never seen any fatal result. He gives it in one-half to two-grain doses in children, and about ten grains in adults, especially in weak and anæmic cases. Children will fatten under its use, and the anæmia will gradually disappear. In the majority of instances he had given it simply dissolved in water, without combining it with any other remedy. He had made post-mortem examinations of cases who had taken this remedy, but had never seen it deposited in the tissues.

Dr. Henry K. Leffmann said that the possibility of a mechanical action should be borne in mind, as the crystals are sharp and not very soluble,—something like the sulphate of potassium used in Dover's powder. He had been surprised that the chlorate of sodium had not been substituted for the potassium salt, on account of its greater solubility.

Dr. J. Solis Cohen said that he had given chlorate of potassium a great deal for the last twenty years. In diphtheria there is a tendency to kidney disease, and the possibility of giving rise to trouble should be remembered. The gentleman referred to by Dr. Shoemaker as recommending this remedy for scrofula seems to use it in the majority of diseases; it appears to be a hobby with him. He gives it simply in solution (one ounce of the chlorate to one pint of water), and also uses it to apply externally to burns, etc. His idea is that it breaks up in the system and yields oxygen. It is worthy of note that the sub-

stances found useful in diphtheria are generally chlorine compounds.

Dr. Leffmann said that, without discussing its therapeutic effects, he wished to observe that we cannot introduce an oxidizing agent into the blood without at the same time producing a corrosive effect. This does not occur from potassium chlorate.

Dr. Shoemaker said that the original paper by Dr. Harkin which he had referred to was very favorably received by the Society before which it was read, and elicited a very interesting discussion.

Dr. Parish said that there is one objection to the use of this remedy in young children, and that is its local irritant action upon the stomach. He had formerly used the chlorate in saturated solution and also in powders, and had frequently noticed that the children were restless after taking it, and in several cases there was vomiting. For its local effects upon the fauces he still continues to use it, but apart from this he had not been able to notice any particularly good effects from this remedy.

Dr. Laurence Turnbull said that he had had considerable experience with this salt, especially since Dr. Drysdale's paper was read. He recalled a case of diphtheria that he had been called to see, where a solution of chlorate of potassium was given in solution (a teaspoonful to a tumblerful of water) almost *ad libitum*. In the afternoon the child became worse; the skin became blue, the kidneys were irritable, there was a strong desire to pass water frequently, and strangury. The child passed into a coma and died. He was satisfied that the large doses of chlorate of potassium had an unfavorable influence upon the patient, and he resolved to give it more cautiously and only in small doses. It is a valuable remedy in aphthous sore mouth and sore throat, especially syphilitic sore throat, and care should be taken to have a perfect solution.

Dr. Atkinson said that he had always recommended chlorate of potassium and tincture of chloride of iron in diphtheria in decided doses, though not in a saturated solution. He had followed this in his practice, and had never seen any bad results.

Dr. Shoemaker said that during an attack of diphtheria, from which he suffered last winter, there had been great irritability of the stomach, and the only thing that he could retain or that gave him any relief was chlorate of potassium. He used it very frequently at his Dispensary for Skin Diseases with good results, beginning with small doses and gradually increasing them. He had taken himself from three to five grains quite frequently.

Dr. Wittig recommended the combination with iron and tonics. He had read that the chlorate might be used as an antiphlogistic agent standing between nitrate of potassium and chloride of ammonium.

JAMAICA DOGWOOD IN NEURALGIA.

Dr. Cohen inquired whether any member had any experience in the use of Jamaica dogwood in neuralgia, which had lately been recommended as a substitute for opium. It is said to have a powerful effect upon fishes. It is a powerful anodyne, relaxing the system, producing salivation and sweating, and does not cause constipation. He had employed it in one case, when the result was doubtful.

Dr. Boardman Reed, by invitation, said that he had used the remedy in two cases of neuralgia of the face which had been suffering for years and had taken opium, morphia, and all the usual remedies. They both had great relief from teaspoonful doses repeated every three hours: one required two doses, the other five or six. In the latter case nausea was experienced after several doses had been taken.

MEDICATED COTTON.

Dr. Laurence Turnbull said that he had formerly found much difficulty in applying iodoform in ear diseases either in substance or in solution in alcohol and glycerin, but this had been recently obviated by a preparation recommended by Dr. Woakes, of London, absorbent cotton being impregnated with a solution of iodoform and dried. This agent is very valuable in affections of the nose and ears attended by chronic discharges. It may also be obtained containing astringents, Monsel's salt, boracic acid, and in other useful combinations, at our leading drug-stores.

F. W.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, SEPTEMBER 23, 1880.

The PRESIDENT, DR. S. W. GROSS, in the Chair.

The etiology of fractures of the cranial base, and the anatomico-pathological reasons for their fatality.

DR. C. B. NANCREDE read a paper with the above title (see page 33).

Dr. H. LENOX HODGE said that the paper presented by Dr. Nancrede was able, original, and instructive. Many of the conclusions would meet the hearty approval of all. He regretted that Dr. Nancrede had not completed his paper by performing and reporting a series of experiments upon the cadaver. The number of post-mortem examinations that can be obtained after fractures of the base of the skull is necessarily limited. The various forms of injury that produce fractures at the base of the skull can be readily repeated on the cadaver. The effects of blows, of falls, and of gun-shot injuries can thus be easily studied.

Clinical observations and experiments have brought out many points of interest. Injuries

to the forehead are followed by fractures of the anterior fossæ, injuries of the temporal regions by fractures of the middle fossæ, and injuries to the occiput by fractures of the occipital fossæ. A fracture at the base of the skull is almost always accompanied by a fissure in the corresponding portion of the vault. The result of a blow or a fall on the head is due not only to the effects produced at the point of impaction, but also to those at the point of resistance. The cause of death after these injuries is due frequently to the direct effect of the vibrations upon the brain itself at the time of the injury, rather than to any secondary effects produced on it by the fracture of the skull.

Dr. SEILER said that he understood Dr. Nancrede to say that the injuries at the base of the skull were due to vibrations excited by the blow or fall upon the cranium, which were transmitted along the best conductor of vibrations, the thicker portions, to the base of the skull, where, by the meeting of different sets of vibrations coming over different routes, they were so augmented as to break the bone. He would like to call attention to the fact that this was an error of pathology, as the thicker portions of the bone were not better conductors of the vibrations than the rest of the base, but that they were capable of transmitting vibrations of greater amplitude. The conductivity of a substance for vibrations depended upon the proper relation of elasticity to density, and he cited as an example rubber, in which the elasticity is much greater than the density, and it is therefore a bad conductor of vibrations.

Dr. Seiler said that in regard to the second point there might be cases in which the vibrations might be anticipated by meeting instead of their amplitude being augmented, and this took place, as he showed by a diagram on the blackboard, where the depression of one wave fell together with the elevation of another one coming from a different direction.

Dr. CHARLES K. MILLS thought that in considering cranial fractures and concussion, and their consequences, the author of the paper should not have overlooked the investigations of Duret on Cerebral Traumatism. This distinguished cerebral physiologist has published the results of an elaborate experimental research and clinical study, under the title of "Experimental and Clinical Studies upon Cerebral Traumatism" (Paris, *Le Progrès Medical*, and A. Delahaye, 1878). The *American Journal of the Medical Sciences* for January, 1879, contains an able review of Duret's work. The cranium is a closed cavity with elastic walls. The elasticity of the skull can be readily proved. Duret mentions an experiment of Félizet, who filled a skull with melted paraffine, cooled it, and let it fall from a height of two and a half feet. The paraffine at the point corresponding to the blow showed a flat surface which indicated a depression of the skull of one-third of an inch. Not only is the skull elastic, but its contents are practically incompressible. A sudden blow on the cranium will therefore be transmitted to all parts within. A strong cask filled with a liquid may be burst by striking on the bung, or by pouring a few ounces of liquid into a long, vertical tube communicating with the interior of the liquid. Experiments of this kind are familiar both to practical men and to school-boys. Liquids transmit pressure equally in all directions, but, the contents of the cranium not being homogeneous, the effects of a blow upon the outside of the skull will be exerted from within outward upon certain regions of the brain and skull more strongly than upon others. The consequences both upon the brain and upon the skull are likely to be more disastrous when a blow or a fall is upon the top than when it is received upon the side of the head. Duret's explanation of this fact is that when the impact is in the transverse axis of the cranium a *cône de soulèvement*, or elevation of the skull, takes place at a point immediately opposite to the *cône de dépression* produced at the point of impact, and in this way the effect of the blow is diminished. When the blow or fall is received on the vertex, this saving cone of elevation cannot be formed, because the region opposite rests upon the spine and will not yield, and because also, perhaps, the structure and shape of the cranial base are such as largely to prevent such a result.

In cases of fracture at the base or at any other part of the skull, fatal effects or serious results, such as fever, paralysis, or convulsions, are not always, and perhaps not usually, due to inflammation set up about the seat of fracture. The researches of Duret here again afford us a satisfactory explanation of phenomena which would otherwise be inexplicable. A blow or a fall sufficient to produce a fracture of the floor of the skull would be more than sufficient to cause the lesions and symptoms, either primary or secondary, which Duret studied under the head of cerebro-spinal shock. By blows upon the head and by injecting liquids within the skull lesions were produced in almost every portion of the brain. Some of these were the following: direct laceration and hemorrhages of the meninges; hemorrhages at various points at the base of the brain; extravasations of blood within the fourth ventricle; tearing of the foramen of Magendie; splitting of the floor of the ventricle; interstitial hemorrhages in the substance of the pons and medulla oblongata; hemorrhagic lesions even in the spinal cord. The symptoms produced by cerebro-spinal shock are, in very broad terms, changes in respiration, circulation, and intelligence, and spasm, tremor, paresis, or paralysis of certain muscles.

In regard to the spasmodic symptoms, in particular, which follow injuries to the base

of the cranium or to other portions of the skull, Dr. Mills believed that at least three explanations might be given of their production: (1) direct irritation of the dura mater by spiculæ of bone, by clots, by spreading inflammation, etc.; (2) direct irritation by similar means of the cortical motor centres; (3) irritation from the effects of cerebro-spinal shock of the centres of the bulbo-pontine region Numerous experiments by Duret have shown that the dura mater contains sensory nerves, readily excited, irritation of which gives rise to reflex spasms or contractures. The irritation is conveyed by these sensory nerves to the motor centres of the pons and medulla oblongata. Local irritation of the cortical motor centres may be caused by meningeal hemorrhages, by friction, and in other ways. By irritation from the effects of the cerebro-spinal shock he meant the rents, extravasations, and secondary inflammations of the convulsive zone of the floor of the fourth ventricle.

Dr. Mills also called attention to the analogy between the consequences of apoplectic shock and those of shock from blows and falls upon the head. In cases of hemorrhagic apoplexy the brain is struck a blow from within, instead of from the outside as in traumatisms. In sudden and extensive hemorrhages, displacement of the cerebro-spinal fluid sometimes takes place. He had recently reported to the Philadelphia County Medical Society a case of hemorrhage in the basal ganglia, followed by effusion of blood into the ventricles, in which the upper part of the floor of the fourth ventricle was found to be split to a slight depth in the median line. He thought it probable that at the time of the apoplectic stroke the cerebro-spinal fluid had been suddenly forced through the aqueduct of Sylvius, and that the walls of the fourth ventricle had been subjected to an outward pressure sufficient to cause a partial rupture. In such cases of apoplexy, besides the direct destruction caused by the effused and spreading blood, lesions similar to those seen after great external violence are usually present. These are small hemorrhages into and beneath the meninges, hemorrhagic spots in the pons, medulla oblongata and cord, etc. Many of the symptoms, immediate and remote, of apoplexy are the same as those of cerebral concussion or sudden cerebral compression.

In closing the debate, Dr. NANCREDE, replying to Dr. Hodge, said that he could only again apologize for the many shortcomings of his paper, no one being more aware of them than himself. Unfortunately, however, owing to the absolute impossibility of giving more time to its preparation, the experiments that Dr. Hodge referred to had to be omitted. Dr. Hodge would bear him out in the statement that he had applied to him for some heads to experiment upon, but that time was wanting. He differed from him, however, as to the ease with which fractures could be produced. It is, indeed, a simple matter to cause an extensive fracture of the skull, implicating the base, but very difficult to produce one involving the base alone, as shown by the specimens and the case related, and which Dr. Nancrede contended gives the key to the causation of the more extensive injuries.

With regard to Dr. Seiler's strictures as to the correctness of the term "conductors of vibrations," he acknowledged their propriety, and would, by his leave, correct it when publishing the paper. Dr. Seiler should recall the fact, however, that Dr. Nancrede in one part of his paper had termed the thickened ridges of bones "reinforcers" of the vibrations. As to the fact that the vibrations might meet and neutralize one another, he had thought that to be so self-evident as to require no statement regarding it. He would append a foot-note which would prevent others from being led astray by this omission.

Finally, as to Dr. Mills's criticisms, he must again say that his paper necessarily was limited to the consideration of certain points only. Perhaps a better title would have been "Some Hints as to the Etiology of Basal Fractures," rather than "The Etiology." He could not, however, agree with Dr. Mills as to the explanation of the slight cases which he had distinctly stated formed the text for his paper. He acknowledged the truth of most of Dr. Mills's remarks, but still thought that the cases described were better explained by his own paper. Dr. Mills made no sufficient allowance for the displacement of cerebro-spinal fluid. Again, experiments do not explain the fact that the bony lesions do *not occur* exactly opposite the point struck, as the "cones theory" would imply, but at certain definite portions of the cranial base, to a marked extent irrespective (with certain limitations) of the point struck. Dr. Nancrede had, it would be remembered, not denied injury to the brain opposite to the point of impact. The cause of death, in the cases cited, did not seem to him due to the cerebro-spinal shock and its consequences, there being no evidences of active disease gradually supervening from the traumatisms *until normal vibrations had been excited in the cranial walls which failed to be conducted to their normal points for arrest, and in consequence irritated the brain and its envelopes.*

Again, Dr. Mills failed to appreciate the fact that when a fracture results the vibrations are chiefly, if not entirely, confined to the bone itself, it being a well-known fact that the more extensive splinterings of the vault, for instance, are often accompanied with but few evidences of injury and irritation of the subjacent brain: so that the constant contusion of certain portions of the base of the brain which are not necessarily opposite to the point struck, but correspond to the fracture, supports the views taught in the paper.

GLEANINGS FROM EXCHANGES.

Recent Investigations on the Antagonism of Quinine and Atropin.—According to the *Lancet* (vol. ii., 1880, p. 176), an interesting contribution to the facts relating to the antagonism between the actions of drugs has been supplied by Panteljeff with regard to two drugs in common use,—quinine and atropin. The salts employed were the chloride of quinine and the sulphate of atropin, and the experiments were made upon dogs, rabbits, and frogs. An injection of quinine beneath the skin of the frog in summer arrests the heart in diastole, but a subsequent subcutaneous injection of atropin causes it to resume at once its pulsations. The appearance of the heart when its action is arrested by the influence of quinine is as if the blood-pressure upon the heart was greater than the cardiac walls could contract upon. If atropin was injected first, so as to cause an acceleration, this was arrested by the quinine. With winter frogs the influence of the quinine was more frequently to cause a gradual retardation in the action of the heart, which was only arrested after a time, with loss of reflex action and death. The injection of atropin did not prevent this, but retarded the heart still more. Microscopic examination of the vessels of the web of the foot showed that the quinine caused a narrowing of the small arteries to one-half their previous calibre, while atropin dilated the vessels. In rabbits it was found that when the heart's action was arrested by quinine, atropin caused it again to beat, and the auricles began to contract before the ventricles. In both dogs and rabbits the blood-pressure in the carotid rose after the injection of quinine, when the pulse was rendered less frequent. It was found that immediately after the injection the blood-pressure suddenly falls, but after a few seconds it rises to a higher degree than before the injection. In small doses the pulse is often accelerated during the increased pressure, but with large doses the pulse is retarded from the beginning. If repeated injections are made, every injection causes, first a sudden fall of pressure, with retardation of the pulse; then the pressure rises, to fall again after a new injection. This initial fall in the blood-pressure is probably due to a sudden contraction of the vessels of the lungs, hindering the passage of the blood into the left ventricle and the aorta. The cardiac contractions become, at the same time, less frequent, but stronger. The arteries of the aortic system then contract and cause an increase in the blood-pressure, and, at the same time, an acceleration of the pulse. Larger doses have a direct influence upon the heart, so that, later, the cardiac action becomes retarded and the blood-pressure falls. The pneumogastrics remain excitable by electricity, but their division exercises no marked influence upon the pulse, especially when the respiration is retarded by the action of quinine. Subsequent injection of atropin accelerates the pulse, even when the pneumogastrics have been divided. In only one observation upon dogs was an arrest of the heart by quinine prevented by atropin. The increase of pressure caused by quinine was disturbed and retarded by the preceding injection of atropin. Direct application to the heart of frogs showed that not only can quinine arrest the action of the heart, but that it can also, under certain circumstances, act as a stimulant to excite it to action, and the effect depends upon the condition in which it is.

A Plea against the Resection of the Ribs in Empyema.—Under this title Dr. Charles A. Leale (*New York Medical Record*, vol. ii., 1880, p. 317) gives several cases in point, and adds the conclusions to which his experience has led him. They are as follows:

He would, as in tracheotomy and abdominal paracentesis, prefer to use the scalpel to open the chest. 1. As a safer procedure, knowing exactly what is being cut. 2. An incised wound is known to heal, if required, with greater certainty. 3. That by using a long, male, silver catheter the most dependent part of the chest can be emptied of its fluid contents, and there is no danger of pricking the lung from change of position or movement of the patient while the liquid is being withdrawn, as noted by Dr. Allbutt. 4. That when pus has commenced to undergo that change preparatory to absorption, the probabilities are that very little, if any, will be produced after the operation if the wound is immediately closed. 5. That in closing the wound under the above circumstances, the little atmospheric air admitted and the small quantity of pus left are very soon absorbed. 6. That if pus again accumulates in the chest, the operation is so easy, the pain so slight, and the closure so rapidly accomplished that a repetition is nothing to be feared, and really causes less prostration than when a large incision is made, and possibly pus found with greater rapidity. 7. That atmospheric air, pus, and blood, even to the extent of about eight ounces, may be absorbed, and that the injured, compressed lung can again resume its normal condition, as is conclusively proved by recorded post-mortem examinations. 8. That when unhealthy decomposition has commenced, the wounds ought to be left open and the part carefully disinfected. 9. That thoracentesis should oftener be performed for the quick removal of fluid from the chest, even, as recorded, during far-advanced phthisis pulmonalis, when relief may be obtained, life prolonged, and painful death averted. The resection of the ribs during the operation of thoracentesis has now been resorted to quite frequently during the past six years in America, Great Britain, France, and Germany,

without adding to the safety of the patient, and in a large number of instances, Dr. Leale firmly believes, has been the means of long procrastinating an apparent recovery, while in others death, it appears, has been the direct result.

FOOD-ADULTERATION.—At the recent meeting of the American Social Science Association (*New York Medical Record*, vol. ii., 1880, p. 331) Professor S. W. Johnson, of Yale College, read a paper on the "Adulterations of Foods, Drugs, and Domestic Articles," the paper being an exhaustive review of the subject. From the long list of adulterations mentioned may be taken the following:

Wheaten flour, with rice, barley, peas, beans, buckwheat, millet, and boiled potatoes; bread, with alum, sulphate of copper; yeast, with alum; baking-powders, with terra alba, such as plaster of Paris, whiting, and kaolin; milk, with sugar, salt, soda and chalk, annotto and turmeric, gum-dextrin, emulsion of hemp-seed, boiled starch, and pulverized brains; cheese, with potatoes, beans, vermilion-red and red chalk, sulphate of copper, arsenic, and corrosive sublimate; lard, with boiled starch, alum, and quicklime; confectionary, with red lead, chromate of lead, and vermilion, Prussian blue, copper, and arsenic; pickles, with sulphuric acid and verdigris; mustard, with wheat flour and turmeric, charlock-seed, cayenne, and ginger; coffee (ground), with wasted acorns, spent tan-bark, spent logwood, mahogany, sawdust, and burnt horse's liver.

In answer, however, to the question, "Are we in the United States liable to suffer in purse and in health from the adulterations that are now practised upon our food?" the answer is a qualified negative. We are not suffering serious loss of goods or of health.

ERGOT-POISONING.—Dr. John M. Keating (*New York Medical Record*, vol. ii., 1880, p. 318) gives the case of a woman recently delivered, to whom, by a misunderstanding, half a drachm of fluid extract of ergot was administered every half-hour until eight doses had been taken, two drachms having been previously given. The entire amount ingested was six drachms within four hours. When seen, the patient's face was of a bluish tint, and she seemed in great pain; the pupils were dilated, the pulse quick, weak, and occasionally irregular; there was no dyspnœa, nausea (no vomiting), buzzing in the ears, and at times a tendency to syncope. The skin was cool and clammy; there were powerful uterine contractions. Dr. Keating loosened the binder, gave her some whisky, and stimulated the circulation by rubbing, and in the space of half an hour the severity of the symptoms had gradually passed away, and the patient was left to sleep off a dose of morphia and bromide of potassium.

SOOTHING OINTMENTS.—In an article on this subject in the *Specialist* (September 1, 1880) Dr. McCall Anderson says,—

One of the most favorite remedies in England is the "Unguentum oxidi zinci benzoatum" of Erasmus Wilson, Bell's formula for which is as follows:

℞ Adipis præparati, ℥v;
Gummi benzoini pulveris, ℥i.

Liquefac, cum leni calore, per horas viginti quatuor, in vaso clauso; dein cola per linteum, et adde

Oxidi zinci purificati, ℥i.

Misce bene, et per linteum exprime.

To this a drachm of rectified spirit, spirit of camphor, or Price's glycerin may sometimes be added with advantage. The benzoin prevents the ointment from becoming rancid and irritating, while at the same time it imparts to it a certain fragrance. It is an excellent preparation, but, owing to the white crust which is apt to form, it is inferior to others when the eruption is situated upon uncovered or upon hairy parts. In such situations the zinc ointment of Dr. L. D. Bulkley, of New York, is preferable: it is composed of pure carbonate of zinc and the ceratum galeni, in the proportion of half a drachm to the ounce.

One of the most valuable of soothing ointments is the "Unguentum diachyli albi" of Hebra, of which the following is the formula:

℞ Olei olivæ, ℥xv;
Lithargyri, ℥iii et ℥vi.

Coque l. a. in ung. moll., dein adde
Ol. lavandulæ, ℥iii.

M Ft. unguentum.

This ointment is likewise unsuitable for hairy parts, on account of its matting the hairs together. More recently several varieties of soothing ointments containing oleic acid have come into use, one of the best of which is the "Unguentum zinci oleatis," recommended by Dr. Crocker, the formula for which is as follows:

℞ Zinci oxidi, ℥i;
Acidi oleici, ℥viii;
Vaselini, ℥ix.

Rub up the oxide of zinc with the oleic acid, and let it stand for two hours; then place in a water-bath until the zinc is dissolved, add the vaseline, and stir until cold. Instead of this Dr. Sawyer has more recently recommended an oleate of lead ointment, which is composed of lead oleate, twenty-four parts; heavy and inodorous paraffine oil, fourteen parts. The lead oleate is prepared by heating a mixture of oleic acid and oxide of lead, one part of the former to eight parts of the latter. It is prepared in the same way as the last ointment, but, in my experience, is inferior to it as a sedative application.

By far the best of all the soothing ointments with which I am acquainted—which was prepared at my suggestion by Messrs. Frazer & Green, chemists, Glasgow, and which is made in the same way as the oleate of zinc ointment—is composed of

℞ Bismuthi oxidi, ℥i;
Acidi oleici, ℥viii;
Ceræ albæ, ℥iii;
Vaselini, ℥ix;
Olei rosæ, ♏v.

I have not only used this ointment with the very best results myself, but those of my professional brethren to whom I have recommended it have professed themselves equally satisfied with it; and one medical man in particular recently informed me that it was the only ointment, of the many which he had tried, which had proved a sedative in his own case.

Instead of merely rubbing soothing ointments upon the inflamed surface, as is so often done, it is always preferable, when at all possible, to apply them spread thickly upon pieces of linen, which should not be too large, else they do not lie evenly upon the inflamed parts.

Boracic Acid in Skin Diseases.—Carbolic acid is doubtless of great value in the treatment of cutaneous affections, but it is a poisonous and irritant substance, especially in the case of young children. Boracic acid is an excellent antiseptic, is non-irritant, non-poisonous, and renders good service in the management of eczema, *e.g.*, in the form of ointment:

℞ Vaselini, ℥i;
Acid. boracic. (impalpable powder), ℈v;
Balsam. Peruvianæ, ℈i.—M.

Or, the boracic acid may first be dissolved in an equal weight of glycerin, and the other ingredients added.

Treatment of Ozæna.—Dr. Wolfrau employed twice a day, for five minutes at a time, aspirations of a solution of tannin and glycerin (two per cent.) preceded by irrigation of the nasal fossæ with one litre of a solution of sea-salt, in the case of a patient who had been affected with a muco-purulent fetid nasal discharge for a year. In a fortnight afterwards he tried a solution of acetate of alumina, at first one-half per cent. and then one per cent. Gradually the nasal secretion became less in quantity and fetidity, the number of irrigations was reduced, and the patient was cured in six weeks.—*Berlin. Klin. Wochenschr.; Specialist*, September 1, 1880.

Treatment of Herpes.—M. A. Fournier (*La France Médicale*) recommends, after washing the ulcerated vesicles of herpes with hypochlorite of soda solution diluted with half its volume of water, that the wound be covered with cotton wool impregnated with the following powder: subnitrate of bismuth, four parts; calomel and oxide of zinc, of each one part. If the eruption is extensive, he recommends absolute rest, the administration of baths with bran or starch, and the internal prescription of opium and bromide of potassium.

Pine-Wool Clothing. — Throughout France and Germany, says the *British Medical Journal*, a considerable reputation has been achieved by the product of the pine-wool fabrics of Remda, in Thuringia. The jerseys, drawers, and underclothing made of this product, woven into warm aromatic undergarments, are much worn, and have a considerable reputation for use as preventives of rheumatic affections, and for protecting the body against sudden changes of temperature in inclement weather.

Simple Method of Reducing Paraphimosis.—M. Bardinet employs the following with success. He inserts the convex ends of three hair-pins, at regular distances apart, beneath the constricting ring, and over the bridge thus formed the foreskin is drawn down with the greatest facility.—*Allg. Med. Cent. Zeit.*

MISCELLANY.

Characteristics of Chian Turpentine.—Prof. Clay contributes to the London *Lancet* the following interesting information regarding this new remedy:

"The pure drug is of such a solid nature that a portion taken between the fingers may be rolled into the form of a pill without adhering to the fingers: thus it is very different from the large number of spurious specimens which have been supplied to the public, and which for the most part have been of a syrupy consistence. The odor of the genuine drug is peculiar. If a portion be softened between the fingers the fragrant odor can be readily perceived, and it is not by any means similar to that of turpentine oil, whilst the spurious kinds smell strongly of the latter substance. The taste of the pure article is characteristic in not being unpleasant. Indeed, it is almost tasteless: I have kept a piece in my mouth for two hours and scarcely knew that it was there. The taste of most of the spurious kinds is very bitter, and so unpleasant that I now rarely adopt the above-mentioned mode of testing the drug. The brittle yet elastic nature of the pure drug is very striking. If a piece is warmed and rolled out, and is allowed to cool, and is then dropped on the floor, it generally breaks into a number of fragments. If a mass is placed in a shallow vessel it usually flattens and spreads over the vessel, the surface being smooth. When the pure drug is placed between two pieces of warmed glass its appearance corresponds exactly with that given in the Pharmacographia. It is best to take a piece of glass, warm it very slightly with a piece of lighted paper, clean it, and then place the drug to be examined upon it; then cover the drug with another piece of glass, and allow both to cool; then by holding the double glass up to the light the characters are readily distinguished. If the drug is spurious, consisting perhaps of strained crude turpentine or Venice turpentine, and so

placed between warm glass, it will present the appearance almost of water. If Chian turpentine is adulterated with Canada balsam, on a gentle heat being applied to the glass on which it has been laid, the Chian turpentine remains in the centre and the balsam flows over the glass, the reason being that the former requires a little stronger heat to liquefy it. If black resin is mixed with Venice turpentine to make the specimens resemble the impurities of the real article, the compound is of a syrupy consistence only, and on heating the mass sufficiently between two glasses the resin is melted, so that the apparent impurities which it presented disappear, while these remain permanent in the genuine drug. Canada balsam, when heated, becomes transparent, and perhaps more so if the heating is repeated, and the smell is of a well-marked sickly odor. If the spurious kind consists largely of resin, and a piece is put on a spatula and a lighted taper applied to it, the characteristic resinous odor is at once obtained.

"The taste, odor, and appearance, then, are the chief characteristics of the drug. If it has a bitter taste, it is not pure; if it has not much taste, as a mixture of resin and Canada balsam, on burning the mass the peculiar odor will reveal its impurity. If the mass does not dissolve in alcohol, but leaves a glutinous residue, then, all other things being equal, it is pure. If it is of a grayish-white or even black color, mixed with impurities, and of a syrupy consistence, it will have a strong smell of turpentine, and is not pure."

MALTINE IN PHTHISIS. By William Porter, A.M., M.D., St. Louis.—There is no complication of chronic disease more common than malnutrition; equally true is it that in such diseases no function demands more attention than the assimilation. After cod-liver oil was urged upon the English profession by Bennett, the proportion of deaths from phthisis to deaths from all causes was lowered from 16 per cent. for five years previous to 1841 to 10.4 per cent. for five years subsequent to 1860. (See Registrar-General's Report.) Dr. C. J. B. Williams (Lumleian Lectures, Lond. College of Physicians, 1862) observes "that the experience of Louis and Laennec gave an average of two years' life in phthisis after it was decidedly developed; but that since cod-liver oil was introduced, he infers from seven thousand cases that the average duration of life has been four years."

Phthisis is pre-eminently a wasting disease, and by exalting failing nutrition, cod-liver oil being little more than a given food, a great advance was made in therapeutics. It has been found, however, that the oil does not in many cases meet the indications; for not only is nourishment needed, but the digestive power is so reduced that but little use is made of the food that is taken. Hence a demand both for nutritious material and for something which will aid food suitable for assimilation. The clinical starting-point in the history of the greater number of cases of phthisis is malnutrition, and when that is guarded against much is accomplished.

After full trial of the different oils, and extract of malt preparations, in both hospital and private practice, I find Maltine most applicable to the largest number of patients, and superior to any remedy of its class. Theoretically we would expect this preparation, which has become PRACTICALLY OFFICINAL, to be of great value in chronic conditions of waste and malnutrition, especially as exemplified in phthisis. Being rich in *diastase*, *albuminoids*, and *phosphates*, according to careful analysis, it aids in digesting farinaceous food, while in itself it is a brain-, nerve-, and muscle-producer.

In practice this hypothesis is sustained. A female patient at St. Luke's Hospital, aged 35, with phthisis, signs of deposit in left upper lobe, losing flesh for six months, poor appetite, and night-sweats, began taking Maltine March 13, 1880. She now weighs one hundred and twenty-one pounds, eats well, has no night-sweats, and the evidences of local disease are much less marked.

Another case of phthisis: A gentleman from Alabama, with all the physical signs of phthisis, rapidly losing health and strength. His was the remarkable gain of ten pounds *from six weeks' use of Maltine.*

Seven pounds' increase in as many weeks is the record of a third patient, a lady of 41 years, who has had no other medication than the Maltine. In these and other cases the increase in strength and mental vigor is in proportion to the gain in weight.

These instances are sufficient for illustration, and are *duplicated many times in the experience of physicians everywhere.* There is a universal reluctance always to testify to results from medicinal preparations, but when, as in this case, the composition is fully known, and the profession invited to investigate the manner of preparing it, there is no reason why the remedy should not receive general approbation, provided it be worthy.—*Quarterly Epitome of Practical Medicine and Surgery, a supplement to Braithwaite's Retrospect.*

THE Chicago *Medical Review* says that "The medical schools of New York, Boston, and Philadelphia which stand aloof from the association of colleges, either by withdrawal from membership or in their failure to place themselves on record as being in harmony with its spirit of advance, occupy a ridiculous position when they impliedly say that the attempt is premature. The difference between these institutions and the Western and Southern members of the College Association is that the latter propose to require of their candidates for graduation not merely the 'evidence,' but three years of genuine study; while the former continue to require two short sessions of lectures, and to dispose of the remainder of the three years by simply re-

quiring 'evidence' of study." It thinks that, in the long run, low-grade schools in the East will scarcely make headway in face of the honest efforts for improvement now made in the West.

HEBRA'S PECULIARITIES.—It is said that, with all his popularity among his pupils and his colleagues, the late Professor Hebra was a thorough despot. He was termed, it is said, the "hospital pasha;" and by his rude language, indecent jokes, and arbitrary bearing he too often excited terror among patients and the more timid of his colleagues. English and American visitors who have been present at some of his clinical lectures have declared that scenes were witnessed and language heard which would not have been tolerated in any other hospital in the world. However, a great teacher he was, and his lectures were delivered in the most classical German.

M. MAURICE KOECHLIN, of Mulhouse, was recently graduated as a bachelor of arts at Rouen, at the age of sixteen years. The remarkable thing in the case is not alone the youth of the graduate, but the fact that he is a deaf-mute, having been born in that condition. His wonderful success, in spite of his great natural disadvantages, has created quite a sensation,

IMPACTED WATERMELON-SEEDS.—Dr. J. H. Stranger writes to the *New York Medical Record*, "On August 3 I removed a pint of watermelon-seeds from the rectum of a patient of mine. He had eaten the melons, seeds and all, and the seeds were so firmly impacted that they had to be removed under chloroform."

TREATMENT OF HYDRARTHROSIS.—Dr. Paquet reports twenty-two cases of hydrarthrosis of the knee-joint, subacute and chronic, treated by immobility and faradization, sixteen of which were cured permanently in from eight to twenty-five days.—*Le Progrès Médical.*

IT will be remembered that some time since Dr. S. P. Chalfant fatally shot Josiah S. Bacon in a quarrel growing out of the dental rubber suits. He has recently been convicted of manslaughter and sentenced to ten years' imprisonment.

ACCORDING to the New York *Medical Record*, registration under the new law has been very general on the part of the profession: two thousand two hundred and fifty is the number for New York City.

DR. WILMS, said to have been the greatest operating surgeon of Germany, and one of the luminaries of scientific and professional Berlin, died recently of blood-poisoning, contracted during an operation.

DR. VERNEUIL, Surgeon to La Pitié Hospital, and Dr. Charcot, Chief Physician of the Salpêtrière, have been made officers of the Legion of Honor.

IT is said that thymol has the property of immediately removing the smell of tobacco.

THE OYSTER.

O mollusk nutritious,
Bivalve delicious,
There's nothing pernicious
In thy succulent dish,
Thou dearly-loved fish!
Heightening our gayeties,
Sweetening asperities,
Softening austerities,
Stomachic, smoothing,
Toothsome and soothing.
However thou'rt galloped,
Stewed, roasted, or scalloped,
Raw, pickled, or fried,
Thou still art the pride
And Queen of the tide!
—*Cincinnati Lancet and Clinic.*

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM OCTOBER 3 *TO OCTOBER* 16, 1880.

HAPPERSETT, J. C. G., MAJOR AND SURGEON.—Assigned to duty as Post-Surgeon at Fort Brown, Texas, to enable Assistant-Surgeon F. Meacham to comply with S. O. 190, c. s., A. G. O., in his case. S. O. 199, Department of Texas, September 29, 1880.

BREWER, J. W., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty at McPherson Barracks, Atlanta, Ga. S. O. 117, Department of the South, October 7, 1880.

LIPPINCOTT, H., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for six months. S. O. 218, A. G. O., October 12, 1880.

POPE, B. F., CAPTAIN AND ASSISTANT-SURGEON.—Having reported at these Headquarters, is assigned to duty at Fort Sully, D. T. S. O. 122, Department of Dakota, October 9, 1880.

DICKSON, J. M., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Vancouver Barracks, W. T. S. O. 171, Department of the Columbia, September 24, 1880.

CRONKHITE, H., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Camp Sheridan, Neb. S. O. 94, Department of the Platte, October 5, 1880.

HEITZMANN, CHARLES L., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for one month, with permission to apply at Division Headquarters for an extension of one month, and to the Adjutant-General of the army for a further extension of two months. S. O. 170, Department of the Columbia, September 23, 1880. Leave of absence extended one month. S. O. 143, Division of the Pacific and Department of California. September 28, 1880.

WILSON, WILLIAM J., CAPTAIN AND ASSISTANT-SURGEON.—Having reported at these Headquarters, is assigned to duty at Fort Meade, D. T. S. O. 121, Department of Dakota, October 6, 1880.

WEISEL, D., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Warren, Mass. S. O. 181, Department of the East, October 8, 1880.

MATTHEWS, W., CAPTAIN AND ASSISTANT-SURGEON.—Having reported at these Headquarters, is assigned to duty at the Cantonment on the Uncompahgre, Col. S. O. 223, Department of the Missouri, October 8, 1880.

SEMIG, B. G., CAPTAIN AND ASSISTANT-SURGEON, Fort Fred. Steele, Wyo T.—Granted leave of absence for one month. S. O. 95, Department of the Platte, October 9, 1880.

PRICE, C. E., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Niagara, N.Y. S. O. 175, Department of the East, September 30, 1880.

GRAY, WILLIAM W., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Dickson, to report to Commanding Officer, Fort Canby, W.T., for duty as Post-Surgeon. S. O. 171, c. s., Department of the Columbia.

GORGAS, W. C., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort McIntosh, Texas, to enable Assistant-Surgeon J. H. T. King to comply with S. O. 190, c. s., A. G. O., in his case. S. O. 199, c. s., Department of Texas.

PHILADELPHIA, NOVEMBER 6, 1880.

ORIGINAL COMMUNICATIONS.

ON WASTING OR "SIMPLE ATROPHY" AS IT OCCURS IN YOUNG CHILDREN FROM INSUFFICIENT NOURISHMENT.

BY LOUIS STARR, M.D.,

Physician to the Episcopal Hospital, and Assistant-Physician to the Children's Hospital, Philadelphia.

CASES illustrating the ill effects of an insufficient supply of food, or of food which, though abundant, is unsuitable in quality, are of frequent occurrence among the out-patients of the Children's Hospital. The condition produced is either one of simple wasting, or of wasting combined with symptoms denoting irritation of the gastro-intestinal canal.

Simple wasting is, I think, most frequently seen in children who have been nursed at the breasts of feeble or overworked mothers, in whom the milk is often both scanty and of poor quality. The symptoms are sufficiently characteristic. There is a gradual loss of plumpness, the muscles grow flaccid, and there seems to be an arrest of growth. The face is pale, the lips pale and thin, the skin harsh and dry or too moist, and the anterior fontanel level or slightly depressed. The temper is usually irritable. When nursed, the child first seizes the nipple ravenously; then, if there is little milk, he quickly drops it, to cry passionately, as if disappointed at not being able to satisfy his hunger; but if the milk is abundant, though thin, he will lie a long time quietly at the breast. The bowels are inclined to constipation. The physical signs connected with the chest and abdomen are negative, and no indication of disease of any special organ of the body can be detected.

Wasting associated with symptoms of gastro-intestinal irritation is more common, and is met with chiefly in infants who are hand-fed. Resulting in the main from an improper diet, it is often encountered where farinaceous food is employed to the exclusion, in great part, of milk; where an infant is allowed or encouraged to bolt bits of table-food and drink tea, and particularly, so far as my experience goes, where the variety of feeding-bottle lately become so popular is used. These bottles have, in place of a plain gum nipple, an arrangement of fine glass and rubber tubing: the glass tubing extending quite to the bottom of the bottle, the necessity of holding the latter and keeping it at a proper angle in feeding is avoided. This seeming advantage is counterbalanced by the minor disadvantage that the child, left to itself, is apt to continue suction long after the bottle is exhausted, and by the great disadvantage that the tubing can never be kept clean. During my last three terms of service at the Children's Hospital it has been my rule to ask for the bottle of every hand-fed infant presented for treatment, and scarcely a day has passed without my seeing several of the bottles referred to. In almost every instance, notwithstanding the most careful and frequent cleansing, the contained milk had a sour odor, and was filled with small curds, while in cases of carelessness the odor was intolerable and the interior of the tubing was encrusted with a layer of altered curd. In bottles provided with a simple nipple, on the contrary, the milk was nearly always perfectly sound and the nipple itself clean.

As there is little difficulty in keeping the bottles themselves clean, there can be only one reason for this difference, namely, in the old-fashioned instrument the nipple is easily removed and as readily inverted and thoroughly cleansed, but in the other there is no way of thoroughly cleaning the twelve or more inches of fine tubing; it cannot be inverted, and the passage of a stream of water or of a small stiff brush can only imperfectly remove the milk clinging to the interior; this, of course, soon undergoes decomposition, and quickly inaugurates change in the next charge of milk placed in the bottle. It is evident that a constant supply of milk thus rendered acid and partially curdled must, like an excess of farinaceous or other unsuitable food, produce irritation of the mucous membrane of the alimentary canal, interfere with the processes of nutrition, and lead to a state in which the features of wasting and disordered digestion are combined.

The following case is a very typical example of this condition:

James ——, æt. 3 weeks, a foster-child, was brought to the dispensary of the Children's

Hospital on April 1, 1879. His nurse stated that he had been in her charge for two weeks, and that he had been sick the whole of this time. The symptoms which arrested her attention were gradual wasting, great restlessness, with frequent, prolonged paroxysms of screaming, and redness and excoriation of the skin in the neighborhood of the genitals and anus. He had been fed upon milk diluted with water, the food being given from a nursing-bottle fitted with the combination of glass and rubber tubing.

At the date of application the child was puny, his surface generally was pale and moist, the muscles were flabby, and there was severe intertrigo of the scrotum, groins, perineum, and inner side of each thigh. His mouth felt hot, the mucous membrane was redder than normal, and the tongue and palate were covered with small patches of thrush. He took his food almost ravenously. There were frequent eructations of sour-smelling, partially-coagulated milk, and the bowels were somewhat constipated. Paroxysms of screaming occurred at short intervals, and greatly disturbed his rest at night; during these paroxysms the legs were drawn upward and moved about uneasily, the feet were very cold, and the abdomen was distended and hard. The heart and lungs were healthy, and the urine was voided freely.

The nursing-bottle was examined. The glass tube which extended to the bottom of the bottle was lined with curd, and a quantity of milk remaining from a supply placed in the bottle about an hour before was sour and contained numerous small curds. This change, it was stated, often occurred, in spite of much care taken to keep the bottle and tubing clean.

Directions were given to substitute a soft india-rubber nipple for the tubing, to keep both the bottle and nipple thoroughly clean, to wash out the child's mouth with cold water after each feeding, and to use a food composed of one part of barley-water to two of milk, with the addition of a tablespoonful of lime-water to each half-pint. Small doses of bicarbonate of sodium, with peppermint-water, were prescribed every three hours. The nurse was also ordered to rub half a teaspoonful of warm olive oil into the skin of the abdomen twice daily, to anoint the surface involved in the intertrigo with oxide of zinc ointment, and to keep the feet warm by frictions with the hand.

The improvement under this treatment was rapid. On April 11 (the day of the last visit) his mouth was cool and free from thrush; there was little eructation; the bowels were natural; there were no more attacks of colic; the sleep was undisturbed; the child had begun to gain weight; and the intertrigo was very much better.

In other cases the symptoms are much more grave. The emaciation progresses to an extreme degree; the skin becomes dry, yellowish, and harsh, and hangs in loose folds over the bones,—and this, although a large quantity of food, such as it is, may be consumed. The combination of great wasting with a voracious appetite is very striking, and is only apparently contradictory, since hunger—the demand of the tissues for reparative material—cannot be appeased by food which, from its bad quality, is incapable of digestion or proper preparation for absorption and assimilation; unsuitable food, too, by irritating the mucous membrane of the stomach, creates a fictitious appetite.

Wasting children sometimes have what are termed "inward spasms." When these spasms occur, the upper lip becomes livid, somewhat everted, and tremulous, the eyeballs rotate or there is a slight squint, and the fingers and toes are strongly flexed. They frequently usher in true convulsions.

These "inward spasms," together with restlessness and irritability of temper, are ordinarily the only indications of involvement of the nervous system; but in a child who recently came under my notice there was a train of very misleading nervous symptoms. The notes are as follows:

Philip ——, 15 months old, of Irish parentage, became an out-patient at the Children's Hospital on April 9, 1880. He was the youngest of five children, all of whom are living and healthy. His father had suffered greatly from rheumatism, and his mother, who brought him to the hospital, looked pale and worn, though she stated that she never felt ill. The child had always been fed at the breast, dentition had progressed regularly, and his health had been good until five days before the date of application, when it was observed that he was more pale than usual, that his movements were more feeble, and that there was a tendency to retraction of the head.

When first seen, his skin was pale, the temperature to the hand was normal, and upon drawing the finger-nail over the surface the tache cérébrale could be faintly produced. His face was listless in expression, the veins of the forehead were distended, and there was marked and rigid retraction of the head, any attempt to move it forward causing cries of pain and being resisted by the contracted cervical muscles. The muscles generally were soft and relaxed. The anterior fontanel was open and was natural in appearance. The tongue was very lightly frosted; there was no indication of pressure upon the gums from an approaching tooth; he took the

breast greedily, and his bowels were moved once or twice daily, the stools being perfectly healthy. There was no alteration in the condition of the abdomen. On physical examination the lungs and heart were found to be healthy, though there was a trifling loose cough; the pulse was regular, and slow considering the age of the child, the beats ranging between 80 and 90 a minute. While resting in his cradle he took little notice, so his mother stated, of what passed in the room about him, but occasionally moved his head restlessly on the pillow and uttered several low, fretful moans. Any attempt at movement, as lifting him up to nurse, was attended by crying.

He was ordered two grains of bromide of potassium, with half a grain of iodide of potassium, in camphor-water, four times daily.

On April 12, being too ill to be brought to the hospital, I visited him at his home. I found him in a moderately clean room in a healthy quarter of the city. He rested passively in his cradle, his head bent backward, his eyelids half closed, his thighs drawn up towards his belly, his arms bent at the elbows, and his hands held up under his chin. There was evidently greater prostration, more wasting, and a nearer approach to stupor. The skin was pale and cool; there was no eruption or maculation; the eyes were sunken and the fontanel somewhat depressed. The breathing was regular, and the pulse was slow and regular, but compressible. The belly was natural in shape, and soft; the tongue was slightly coated; the bowels were moved two or three times daily; there was no vomiting, and the appetite was good. In order to test his capacity for feeding, his mother was directed to put him to the breast; the child began to whimper as soon as he was moved, but when the nipple touched his lips he quickly seized it, made several forcible efforts at suction, and then dropped it with a cry as of disappointment. The breasts were examined and found to be small and flabby, and to contain little or no milk. This discovery suggesting an alteration in the diet, directions were given to feed the child chiefly upon cow's milk, and to reserve the breast-milk for the night. An attempt was also made to increase the flow of the latter by advising an improvement in the mother's dietary. The bromide of potassium mixture was continued.

On April 14 the symptoms were still more serious. When closely questioned, the mother reluctantly admitted that she had not fed her baby as ordered, having no means of procuring milk, and further that, her husband having been out of work for several weeks, her own food had been reduced to a very moderate allowance of bread and tea. In consequence the flow of milk had gradually failed, particularly so during the preceding two days, the knowledge of her child's wants and her total inability to supply them producing an exceedingly nervous, despondent condition, and increasing the effect of the starvation diet.

She was readily put in the way of obtaining substantial relief, and after some trouble reassured and persuaded to persevere in the care of her baby. Improvement began simultaneously with the administration of food; the partial stupor, the retraction of the head, and the depression of the fontanel soon disappeared; the little patient began to gain flesh and color, and his muscles became more firm. The bromide of potassium was stopped, and two drops of the syrup of the iodide of iron were given three times daily.

On April 30, the date of the last visit to the hospital, convalescence was thoroughly established. On September 21 the child was in good health.

In this case the retraction of the head, the boring of the head into the pillow, the peculiar decubitus, the general hyperæsthesia, the semi-stupor, the marked prostration, the slowness of the pulse, the tache cérébrale, and the vomiting suggested the existence of tubercular meningitis; but this opinion was reserved on account of the absence of many characteristic features of the disease. Thus, the open fontanel was level; the belly was natural in shape; the bowels were the reverse of constipated; the respiration and pulse were regular; and there was no hydrencephalic cry. Furthermore, no account could be obtained of an initial stage of slowly-failing health, and in other respects the course of the illness was different from that of the suspected disease. At the same time, the idea of such symptoms being due to partial starvation was not entertained until they began to disappear almost immediately upon an increase in the quantity of food. Taking a retrospective view, however, it is easy to refer the anomalous symptoms to an intensely excitable nervous system, — a condition depending upon insufficient nourishment, and differing merely in degree from that leading to the "inward spasms" already referred to.

In a paper on "Starvation Fever," recently read by Dr. Da Costa before the College of Physicians of Philadelphia, three cases are detailed in which a still different set of symptoms were noted.

The first case, a girl aged 3 years, had frequent vomiting, great weakness, giddiness, a feeble and rapid pulse, fever, and loss of vision. Death took place on the thirteenth day.

The second, a pallid, badly-nourished boy 4 months old, had repeated convulsions and a petechial eruption. Death occurred at the end of twenty-four hours.

A post-mortem examination was made in both instances, and, besides minor alterations, the gastro-intestinal mucous membrane was found to be pale and thin, and there was an effusion of serum into the pleural sacs.

The third patient, a feeble girl of 3½ years, had fever, followed in a short time by bronchitis, which subsequently ran into broncho-pneumonia. Recovery took place on quinine and a supporting treatment. The bronchitis and broncho-pneumonia undoubtedly depended only indirectly on the starvation, which, by leading to weakness and ill health, rendered the child very susceptible to the ordinary causes of catarrh.

In the treatment of wasting from insufficient nourishment the first thing to be attended to is the diet. Without entering at length into this subject, it may be stated, as a general rule, that in selecting a diet the object should be to fix upon one which is suited to the age and digestive powers of the child, so that he may be able to digest, and therefore be nourished by, all the food consumed.

At the hospital I have found that children under twelve months, who have to be either partially or entirely "brought up by hand," ordinarily do well upon cows' milk with lime-water or with barley-water. The food should be administered from a bottle capable of holding half a pint, made of colorless glass, so that the least particle of dirt may be readily seen, and provided with a soft india-rubber nipple. The whole quantity of food intended to be given in a day should never be prepared at once, but each portion should be made freshly and separately at the time of administration. Thus, a bottle such as described, as nearly absolutely clean as possible, may be filled with a mixture of one part of lime-water to two or three of sound milk, or with one part of barley-water to two or three of milk, to which may be added from one to four teaspoonfuls of cream and one or two lumps of cut loaf-sugar; the nipple (also perfectly clean) is next applied, and the bottle placed in hot water until the contents become warm, when it is ready for the child.

The degree of dilution of the milk and the proportion of cream added vary, of course, with the age. Lime-water is used as the diluent when there is frequent vomiting or acid eructation, barley-water* when it is desired to prevent the formation of a large compact curd.

After the digestion has been brought into good condition by such a diet, the food may be cautiously increased to the point suitable for a healthy child of the same age: for instance, at eight months from two to four fluidounces of thin mutton- or chicken-broth, free from grease, may be allowed in addition to the milk; at twelve months the yelk of a soft-boiled egg, rice and milk, and carefully-mashed potatoes; and after sixteen months a small quantity of finely-minced meat.

Once daily the patient should be bathed in warm water, or, at least, sponged over with warm water, and every morning and evening a teaspoonful of warm olive oil or of cod-liver oil should be gently rubbed into the skin, especially of the abdomen and chest. At the same time the belly should be completely covered with a soft flannel binder, and the feet kept warm. In this way attacks of colic, if not entirely prevented, are rendered much less frequent and severe.

When there is intertrigo, cleanliness and the free use of oxide of zinc ointment usually suffice to effect a cure.

Of medicines, bicarbonate of sodium, pepsin, and cod-liver oil are, perhaps, most useful. Cod-liver oil should not be given until the digestive powers have been brought into a comparatively normal state by proper food, antacids, and digestants. It seems to be most easily borne when given in emulsion, and may be advantageously combined with lacto-phosphate of lime or with the hypophosphites.

Such symptoms as constipation and diarrhœa demand, of course, appropriate treatment.

CASE OF CEREBELLAR ABSCESS.

BY LAMBERT OTT, M.D.

M. S., æt. 20, married, American by birth, always delicate; gave a good family history; was nursing first child, then five months old. In her eleventh year she had scarlet fever, which left a chronic otorrhœa. This discharge was purulent, now and then ceasing, to return again in a short time. This trouble, which was confined to the right ear, produced entire deafness on that side. The

* Barley-water is made by putting two teaspoonfuls of washed pearl-barley in a pint of water, boiling down to two-thirds of a pint, and straining.

membrana tympani was destroyed, and the discharge blocked up the canal, preventing a further view,—evidently an otitis media. Saturday, October 4, she moved, and retired that evening feeling very tired. The next day being Sunday, she rested, and made no particular complaint. Monday, October 6, she worked hard all day restoring order among her household goods, at the same time complaining of a dull, persistent headache, with great lassitude. She accomplished her work, and retired in the evening with an excruciating pain in the right side of the head corresponding with the side of the diseased ear. Tuesday she remained in bed, complaining of pain, great thirst, and fever. She then came under my notice. On first noticing her she was lying still, respiration imperceptible, very anæmic-looking, eyes closed, and face quite expressionless. In other words, she looked as one dead, and when informed that a physician was present she did not move. After arousing her, she repeated the above history of the headache, etc. Her condition was then as follows:

Pain still in right side of head, excruciating at times, never intermitting; no discharge from the ear; answered all interrogations intelligently, as one who was in every respect rational. After repeating some of her history, she prayed for death to relieve her from this intense suffering. Tongue was coated, dry, and quite red at the tip; when asked to protrude it the mouth was opened quickly, and, without any quivering or deviation to the side, was shown to its fullest extent. Pupils were normal and sensitive to light; no squint; no paralysis. Some fever, temperature being 101° F. in axilla; respirations 16; pulse 60, soft, and compressible; bowels very constipated. Her sleep was continually interrupted by the intense pain in the head, causing a moan that was audible in all parts of the house. Anodynes in large doses were given, with temporary relief. The sleep produced by morphia was somewhat refreshing, though on awakening she was greeted with the same pain. The neck was stiff, the patient moving it like a person having a large carbuncle on the post-cervical region. When she did apparently sleep without being under the influence of an anodyne, delirium of a passive nature was manifested. During the moaning she would turn from one side to the other, and then return, keeping this up for five minutes at a time. When moving or turning, muscular power was not in the least defective, lifting her limbs with great celerity, as one possessing the full strength of health. All these movements, this moaning, etc., occurred during an exacerbation of pain in the head, and as soon as it remitted she would fall into a death-like slumber. Questions were yet answered intelligently and without hesitation. Later, she was unable to get out of bed, and, when lifted, complained of severe vertigo,—so much so that her head was supported by an attendant while one held the body in position enabling her to pass water, which was done without difficulty. Urine contained no albumen. The extremities were moved when asked, and jerked quickly from the spot when pricked with a pin. Four days before death the temperature fell to 97° F. in axilla, pulse 56, and respirations 12 per minute.

From this time on there were no new symptoms. The right-sided headache persisted with continuous moaning, the patient not becoming at any time unconscious or seeming irrational. Just twelve hours before death she conversed about her trouble quite intelligently, communicating some of her symptoms. At the same time she was raised in a sitting posture for the purpose of administering some milk. Deglutition was then attended with some difficulty, three efforts being made before a tablespoonful of fluid was swallowed. She begged to be let alone, as it was very distressing to be handled. Noises did not seem to create any disturbance. Death was easy, taking place during one of those quiet slumbers, those in the room not knowing it until feeling the coldness of the extremities, and finding themselves unable to arouse her.

Autopsy.—Eleven hours after death, rigor mortis well marked. The external appearances of the body were peculiar, and may, perhaps, have been in some way connected with the pathological condition. There was ecchymosis of the left side of the entire body except the head. The right side was free from any such phenomenon. The patient was lying on her back during the dying hour, so that it could not have been produced by the force of gravity.

It is well known that brain-lesions on one side produce abnormalities on the other side. The disease was situated on the right side and the blood-stasis on the left. It may be merely a coincidence. Nothing of this nature was noticed previous to death. On sawing through the cranium a very offensive odor escaped, producing an audible puff, compelling us to relinquish our labors until the room was ventilated. After removing the calvarium, I found the brain in its external appearances healthy; superficial veins very much distended with coagulated blood. Removing the brain from the skull, and accidentally running the hand over the right side of the cerebellum, I found it quite soft and doughy to the touch; on incising it a very offensive greenish pus occupied a cavity involving nearly the entire right lobe. This cavity was irregular in its outline, and the walls were composed of shreddy, disintegrated brain-tissue. About one and a half ounces of pus were collected. The odor was detected by the friends in the neighboring rooms. The dura mater covering this lobe was healthy, but the pia mater and arachnoid were opaque, thickened, and in spots somewhat disintegrated. The left

and middle lobes of the cerebellum were healthy, only showing a little congestion. In other respects the remaining part of the brain presented nothing abnormal. The petrous portion of the temporal bone was normal; no caries. Internal ear not examined. No morbid connection between ear-trouble and abscess could be found.

Dr. M. Franklin saw the case with me, and pronounced the diagnosis of abscess of the brain. One can plainly see, from the symptoms mentioned, that locating it in the cerebellum would have been guess-work. Experience teaches us that abscess of the brain caused by chronic suppurative otitis is generally located in the cerebrum, and then you have convulsive movements, with mental disturbances. Cases of cerebral abscess have been reported where the patient was rational throughout the entire trouble, not having the slightest symptom to point to such a grave brain-lesion; so that localizing an abscess in the brain is a mere matter of conjecture, though there are instances where a positive diagnosis was declared, and confirmed by post-mortem. This case, in its bearing upon the functions of the cerebellum, does not give any new developments, but, on the contrary, seems to discredit some results deduced from pathological observations, giving the cerebellum a special function from the prominence of one of the symptoms.

One result deduced from experimental research is unsteadiness of gait. One week before death she was fully able to get out of bed to relieve her bowels, and nothing in the way of incoördination of muscular power was noticed. Weakness was prominent, requiring assistance to enable her to return to bed, and when once there she could move the extremities perfectly. There was really no definite test made to ascertain whether there was a loss of coördination; the inability to move well was due to great prostration and weakness, and as soon as the vertigo passed off, which generally happened after being erect for a few minutes, she could stand alone and move her limbs readily with a little assistance.

Another symptom advanced by some, as in a case reported by Dr. Tyson (*Amer. Jour. of Med. Sci.*, July, 1877), is a disposition to fall or pitch forward, combined with persistent vertigo. The patient described this as a sensation as though a heavy weight lay in the front part of the head, or as though his head was too heavy and tended to fall forward and downward on his breast. Such was not the case in this instance; if anything, she was disposed to pitch backward and throw herself from side to side, this occurring only during exacerbations of pain, to which cause I attributed it, and not to any influence produced by the diseased cerebellum. On being lifted up in the sitting posture to take nourishment her head would fall back and she appeared unconscious, but the contrary was ascertained by requesting her to drink, when there was a prompt response.

Nothnagel (*Berliner Klinische Wochenschrift*, April 15, 1877) says, "Sometimes disease of the cerebellum causes no symptoms during life which could indicate any brain-lesion, even though an extensive destruction of cerebellar tissue exists." Farther on he states that disturbances of coördination occur only when the median lobe (vermiform processes) is directly or indirectly affected by the disease. My case seems to illustrate the above assertions. Were it not for the dull, persistent, gnawing headache, with a history of a chronic discharge from the ear, the diagnosis of brain-trouble could not have been conjectured. Motor disturbances were absent. The entire right lobe was occupied by the abscess, but the middle and left lobes were free from disease. Dr. Kelp (quoted in *Monthly Abstract*, December, 1878) relates the case of a peasant suffering with cerebellar disease, in whom a post-mortem confirmed the diagnosis. He disproves the opinion advanced by Nothnagel, that disturbances of coördination occur only when the median lobe (vermiform processes) is directly or indirectly affected by the disease. The middle lobe was in no way affected, though motor disturbances, such as the gait of a drunken man and a tendency to fall backward, were present; a few months later paralysis set in.

My case, as many others, assists in settling the question as to a part of the function of the cerebellum being connected with intellection. A patient suffering with an abscess involving the entire right lobe of the cerebellum, able twelve hours before death to hold a rational conversation, is incontrovertible evidence. Other symptoms mentioned in published cases were not present in this one. They were probably due to some undetected coexisting affec-

tion, or merely a coincidence. Death was by exhaustion, the vital powers gradually wasting away, as manifested by the anæmia, debility, and emaciation.

The clinical history of this case has been somewhat detailed, and I have indulged in frequent repetition. As the case is unique, I have purposely gathered as many facts as possible, in order that those who make a special study of these organs may have the benefit of a complete history.

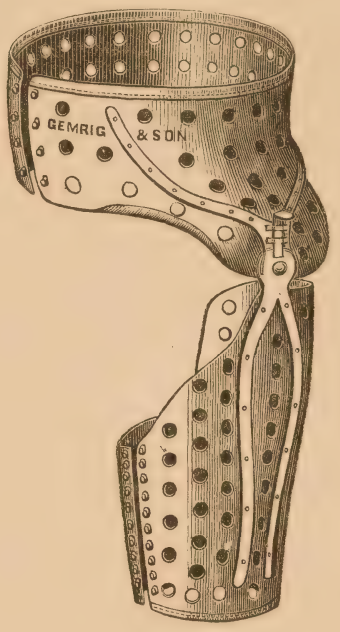
1601 COLUMBIA AVENUE.

HIP-INJURIES, INCLUDING HIP-JOINT DISEASE, AND FRACTURES OF THE FEMORAL NECK, SPLINT FOR.

Read before the Philadelphia Academy of Surgery, June 7, 1880,

BY DE F. WILLARD, M.D.,

Lecturer on Orthopædic Surgery in the University of Pennsylvania.



I DESIRE, in connection with the exhibition of the accompanying splint, not only to call attention to its adaptability to ununited or badly-united intracapsular fractures of the femur, but also to recommend it as an exceedingly useful support in the disabilities following sprains, lacerations, twists, and dislocations (congenital or traumatic) of the coxo-femoral articulation. Of its use in hip-joint disease, I would say here that it is of the greatest advantage in non-acute cases in the first stage, and in a large number during the other stages.

I have for several years been in the constant habit of fixing this joint in fractures of the upper portion of the thigh, and in all hip-injuries and diseases, by permanent dressings of binders' board, starch, felt, plaster of Paris, silicate of soda, etc., especially in the case of children; but the great inconvenience—in fact, the impossibility—of sitting while encased in one of these dressings, if properly applied,—*i.e.*, so as to embrace the thorax,—did not force itself upon my mind until I was obliged personally to resort to the use of such a dressing for the disability following a laceration of the ligamentum teres caused by a violent twist of the leg.

One has but to try the experiment to find that a position other than standing or lying is absolutely incompatible with comfort or the power to pursue any ordinary avocation.

I had often wished to make a joint in my hip-disease dressings, especially in adults who were obliged to attend to business, but, although familiar with the use of leather and felt for spinal dressings, it had not occurred to me to apply them to the hip until I chanced to see a leather apparatus for the relief of a paralytic trouble.

The difficulty with an ordinary jointed splint, however, would be that it would not put the hip perfectly at rest; and I accordingly have had Mr. Gemrig make me the steel joint which you see here, and

which can be locked and unlocked at pleasure, thus rendering the hip perfectly fixed until just at the moment of sitting, when by lifting the bolt (which can be easily done through either a gentleman's or lady's clothing) a perfectly movable joint is secured.

The method of constructing this apparatus is first to make a mould, by plaster of Paris bandages, of the body as high as the sixth dorsal vertebra behind and the lower limit of the ensiform cartilage in front, in order to secure a firm thoracic support; thence downward, covering in the pelvic region as low behind as the commencement of the internatal crease and in front to the summit of the pubis; thence over hip, buttock, and thigh to a point about three inches above the knee-joint. This

mould can be best taken over a light pair of bathing or other closely-fitting drawers. When thoroughly hardened, it is to be slit up, removed, and from it can be made a plaster cast which will be the exact shape of the individual to be fitted, every point and irregularity being represented.

Upon this cast wet leather is stretched and rubbed and worked until it exactly conforms itself to the surface, when it is allowed to dry *in situ*, the result being a perfect fit.

This leather is so tanned by Mr. Gemrig that, while it is exceedingly light, it is perfectly hard and tough, being much better than sole-leather or raw hide.

The above process, though costly, gives a most beautifully fitting apparatus, but I believe that, as the splint is to be worn outside of underclothing, a sufficiently accurate splint could be secured by simply applying the wet leather directly to the person of the patient, shaping it, and allowing it to remain in place a short time until it had hardened just enough to retain its conformation, thus avoiding both the plaster mould and the second cast, and saving considerable expense. The first-mentioned plan, however, is by far the better one.

When thoroughly dry, the body and thigh portions are separated, and connected by a joint attached to two spreading steel arms, as seen in the drawing.

This joint must be a strong one, and should be made double,—*i.e.*, not with a simple rivet, but by the same process as is employed in artificial limbs.

In the lower section is a mortise or slot (*a*) into which fits the bolt (*b*), worked (through the clothing) by the head (*c*), and thus perfect fixation is secured.

This bolt slides easily through the eyelets (*d*, *e*), and is retained in its place when lifted by a spring pressing like a finger against its side. The unlocking can be done in a second, during the act of sitting down. The whole splint is perfectly simple and can hardly get out of order. It is to be laced down the front of the abdomen and thigh.

The steel thigh-pieces could be united into one and continued down to the shoe; but, even though this be done, I consider the enveloping thigh-band as one of the essentials for fixation.

The numerous openings (*f*, *g*, *h*) render the apparatus lighter and give slight vent for exhalations. The total weight for a man weighing two hundred pounds is but forty-five ounces.

The joint allows only the hinge-motion, a matter which is of decided advantage in twists or lacerations, and also in hip-disease, where the round ligament is involved, as rotary and lateral motions would tend to prevent the needed repair.

To render the apparatus comfortable, it is necessary to cut away certain portions after the patient has worn it, especially the part in front beneath the ribs and above the groins. This can be narrowed down greatly so as to give comfort in sitting, for as the leather is stiff all necessary support is gained by the broad posterior portion, which embraces pelvis and thorax. The edges can then be padded with curled hair over salient points, and it will be found that greater ease is obtained by taking its weight off the hips by means of suspenders over the shoulders.

When locked, it is surprising how the weight of the body is transferred to the thigh through the medium of the steel without any strain upon the natural joint.

In the disabilities following injury I can testify that it is of the greatest service, and I have found it of marked benefit as a support in the late treatment of morbus coxarius, enabling fixation or mobility as desired, and so taking off weight from the impaired joint-structures that the crutches can be dropped at a much earlier period than would otherwise be safe.

It is applicable to a limited number of hip-disease cases,—*i.e.*, those in whom the inflammatory symptoms are not acute, in either first, second, or third stage. It should always be used, of course, in connection with the plan of crutches, and a high shoe upon the sound foot. Thus combined, I believe that it furnishes all the desirable points to be gained in the treatment of this terrible disease, since, while it gives absolute fixation at will, it also allows the patient to go about his ordinary out-door pursuits and yet to sit at comfort. All hip-disease splints do good only by fixation, and there is not one which is effectual if the weight of the body is thrown upon the limb.

To supply the lacking power of steadying the pelvis upon the thighs in cases of fracture of the femoral neck, and in instances of congenital dislocation of the head of the thigh-bone, I believe this splint

offers great hope, although I have not, until recently, had opportunity of testing it, and, of course, the future alone can decide.

1626 CHESTNUT STREET.

A CASE OF EMPYEMA WITH A GASTRIC FISTULOUS OPENING—TREATMENT WITH SULPHIDE OF CALCIUM—RECOVERY.

BY THOMAS H. STREETS, M.D.,
Passed Assistant-Surgeon, U.S.N.

EDWARD J., ordinary seaman, aged 22, a native of Sweden, received an injury while employed in the English merchant-service. He was engaged in turning a boat bottom side upward on the deck of the ship, when he slipped and fell beneath the boat, the gunwale striking him on the left side of the chest. He was immediately taken to a hospital in Lisbon, where he remained six months. Twice subsequently he received hospital treatment for shorter periods for the same injury. He enlisted in the United States naval service, January, 1878, and in the March following was admitted to the sick-list of the ship on which he served, with sharp, stabbing pains in the left side and symptoms of pleuritic effusion. In May he was sent to the Shanghai Civil Hospital, where he remained under treatment for ten months. March 1, 1879, the patient was transferred to the United States Naval Hospital at Yokohama, Japan. The hospital-ticket which accompanied him gave his condition as follows: "Thin and debilitated, and is said to occasionally cough up a pint or so of blood. Has occasional comatose attacks, wherein he takes nothing for twenty-four hours. Pulse 96, respiration 56, this morning" (February 4).

The patient's condition was considered very critical at the time of his admission. He was too feeble to walk, and could speak only in a whisper; he afterwards rallied from the fatigue of the journey, and was able to answer questions. He complained of constant pain in the left side, which was sometimes lancinating. There was so much tenderness and soreness over the whole front of the chest-wall below the nipple that he shrank from the slightest touch with the hands. There was no bulging of the left side; the intercostal spaces were sunken and the side slightly retracted. No movement of the intercostal muscles; ribs fixed, and respiration largely diaphragmatic. Recti muscles hard and knotted from constant action in respiration. The stomach was forced up under the ribs, and probably adherent to the diaphragm. Percussion-sound below very resonant; lung partly collapsed; respiration mostly bronchial; a faint vesicular murmur heard above; moist râles numerous; respiration on the right side exaggerated. There was no area of heart-dulness; the heart was displaced backward, and the sounds were almost inaudible. The lungs in this case probably became adherent to the heart, and drew it away from the wall of the chest.*

In addition to these thoracic symptoms, the patient was troubled with vomiting of blood and pus. Food occasioned vomiting, and it could be taken only in small quantities at a time and in a liquid form. The vomited matter, when not mixed with the food, was usually bright red, flecked with pus and with occasional streaks and spots of black, grumous blood. He likewise evacuated blood and pus through the intestines, and a constipated condition of the bowels added materially to his disquiet. According to the patient's statement, before he began to evacuate the pus through the stomach and bowels the left side of the chest was bulged out more than the right side, but immediately after this trouble began it subsided. At first, cough was not a prominent symptom in the case, but it became more marked later, the breath became fetid, and he expectorated considerable quantities of matter.

At times the patient would be bright and cheerful, feeling stronger, and desiring food and to be up and about the ward. The hemorrhages would diminish and breathing become freer,—not so diaphragmatic in character, and râles fewer. This state, however, usually lasted but a short time, when he passed into the opposite condition; he became very irritable, refusing to take anything, and would eventually lapse into a semi-comatose state. He lay on the affected side, breathing rapidly and laboriously, with tracheal rattling. The vomiting would cease and the pulse become a thread. In the warm weather of summer he required extra blankets on his bed and hot-water bottles to keep his

* Art. "Pleurisy," Ziemssen's Cyclopædia, p. 651.

extremities warm. He invariably rallied from these semi-comatose states when the vomiting recommenced, and they were probably occasioned by some obstacle to the free discharge of pus from the pleural cavity. As long as there was a free discharge he apparently suffered no serious discomfort, but as soon as the fistulous opening was blocked up he lapsed into the state just described. He continued in this way, up and down, for three and a half months, with death at any time expected. Milk and wine — the former with lime-water — were administered continuously. The only drugs that were given were Basham's mixture and an occasional tonic when the stomach would tolerate one.

It will hardly be doubted, I think, that we had here to deal with a fistulous opening from the pleural cavity into the fundus of the stomach. We have a history of injury to the chest-wall; a subsequent attack of pleurisy, with bulging of the left side from the accumulation of fluid, and its sudden subsidence when the discharge of pus began through the stomach and bowels; the symptoms of chronic pleurisy when he came into the hospital; the abnormally high position of the stomach under the ribs, and the tympanitic resonance of the lower portion of the chest.

On June 16 I began to give calcium sulphide, one grain daily, in one-fifth-grain doses. The aqueous solution was prepared freshly every morning, as recommended by Ringer. I was induced to give this medicine a trial on account of the strong testimony in its favor by Ringer in his "Medical Therapeutics," hoping that it might have a wider range of usefulness than in the treatment of boils and scrofulous abscesses, and that it might influence favorably suppurating surfaces generally. Improvement commenced immediately the administration of the medicine was begun. The cough gradually ceased, and likewise the vomiting. Formerly the patient shrank from the slightest contact of the hand to the left side; on the 20th of June, or on the fourth day after he began taking the remedy, that side could be percussed and handled as much as desired, and no soreness or tenderness complained of. On the 25th I find it recorded that there was no further vomiting or purging of blood and pus; no cough; general health greatly improved; getting stronger daily; good appetite, and can eat the regular hospital ration. Lung expanding; vesicular murmur much louder.

June 30, a Board of Medical Survey, composed of three medical officers of the navy, was held upon the case. He was considered unsuitable for further naval service, but was deemed in a fit condition for discharge from the hospital and the service. On July 2 the recommendation of the Board was carried into effect, and the patient commenced business in Yokohama, as a saloon-keeper, with the money which had accrued to him while sick.

U. S. Naval Asylum, Yokohama, Japan.

HOMATROPINUM HYDROBROMATUM.

BY P. D. KEYSER, M.D.

On the 8th of August, 1879, Prof. Ladenburg, of the University of Kiel, presented to the Berliner Academie der Wissenschaften a new derivative from belladonna, which he had discovered and called homatropin or homatropinum hydrobromatum. It is an oxytoluyltropein, and formed by the treatment of amygdalinate of atropin (*mandelsauren atropins*) with hydrochloric acid.

In the winter of 1879–80, Prof. Ladenburg gave a solution to Prof. Völckers, of Kiel, to test its mydriatic power in his ophthalmological clinic, who reports (March, 1880) "that he found a one-per-cent. solution dilated the pupil in about ten minutes, but in the greater number of cases not *ad maximum*. Often a slight reaction of the pupil remained. The accommodation is also paralyzed, but not so completely as by atropin. Already in six hours has the action of the homatropin considerably passed off; and after twelve to twenty-four hours every trace of mydriatic action and paralysis of accommodation is gone.

"He believes that homatropin will replace atropin in cases where it is necessary to dilate the pupil for the purpose of making a thorough ophthalmoscopic examination of the fundus, etc."

After this discovery by Prof. Ladenburg, Mr. E. Merk, chemist, of Darmstadt, made the salt, some of which he sent to Prof. v. Arlt, in Vienna, for use, and which he (Arlt) handed to his assistant, Dr. E. Fuchs, for trial, who gives his examination thereof in an article in the June number, 1880, of

the *Centralblatt für Praktische Augenheilkunde*, as follows:

"My experiments were made on a number of healthy persons, and in one eye a one-per-cent. solution of homatropin was instilled, while in the other a solution of atropin (1.5000 and 1.10,000) was dropped.

"The accommodation and enlargement of the pupils were at first examined every five minutes, and further on every two hours. The experiments gave the following results:

"1. The one-per-cent. solution of homatropin caused a dilatation of the pupil in twenty minutes, which reached its maximum in sixty to seventy minutes. The pupils were then 7 mm. and over in diameter, but still not as large (well dilated) as where a stronger solution of atropin was used; there was also a slight ability of reaction remaining.

"After two to three hours the action began to recede, and after five hours generally nothing was noticeable. After ten to twelve hours there was not the least trace of dilatation; in some cases the pupil was smaller than before the instillation. This is also sometimes observed after the discontinuance of instillations of atropin.

"In comparison with a weak solution of atropin (1.5000 or 1.10,000, the action of these strengths was almost the same), the dilatation of the pupil began ten minutes later than with the homatropin. In some cases it reached the full extent, while in others, not so great as in the homatropin. After twelve hours the mydriasis is very perceptible, particularly when comparing it with the other eye, in which homatropin had been instilled, and especially when the pupil is frequently smaller than before the beginning of the examination.

"2. The paralysis of the accommodation begins ten to twenty minutes after the instillation of the homatropin, and reaches its maximum in forty to eighty minutes. It was, like the dilatation, never absolute; in one case there was still 1.5 D. remaining. After five hours the paralysis of accommodation had passed entirely away; in some cases the near point approached nearer than it was before the instillations.

"After the use of a weak solution of atropin, the paralysis of accommodation begins in about the same time as with homatropin, reaches, however, a much less degree, and passes off as quickly as when the homatropin is used. Also here, a recession of the near point for a short time after the paralysis of accommodation had passed away could be observed.

"The comparison of homatropin with atropin in weak solutions gives, in relation to the accommodation, hardly a difference; but as to the dilatation of the pupil, the action begins earlier and passes off sooner than with atropin.

"Herein lies the superiority of the homatropin when it is desired to dilate the pupil for ophthalmoscopic examination. Generally after five hours the pupil has its normal size, and the patient has no further trouble."

Having procured some of this salt for the purpose of studying its action in the eye and comparing it with that of atropia and duboisia, I began the instillations with a weak solution of one grain to the ounce of water, then gr. ij up to gr. x ad ℥i.

My results accord exactly with those of Völckers and Fuchs, that complete paralyzation of the accommodation does not take place in a great majority of cases, and that the pupil is not always dilated *ad maximum*.

In the weaker solutions I think there is not sufficient strength to gain these points, while with the stronger solutions there is so much irritation as to cause an antagonistic action in the circular fibres of the sphincter pupillæ, just as we find in all irritations of the conjunctiva and cornea, causing some contraction of the pupil.

Even with a one-grain solution there is a slight irritation of the conjunctiva, which, however, soon passes off; but when a four-grain solution is used, in five or six minutes there come on a severe burning, smarting pain, and hyperæmia of the conjunctiva, which continue for some time. With an eight- or ten-grain solution quite a severe acute conjunctivitis arises, often requiring applications of cold water to subdue it.

This irritation alone will prevent its general use or displacement of atropia or duboisia, except in weak solutions to dilate the pupil for a short time to make an examination of the fundus.

In comparison with duboisia, I find that it does not begin its action any sooner, but passes off much more readily; completely in six to twelve hours, while duboisia requires from one to four days, according to the strength of the solution used.

Duboisia has also the advantage that it does not irritate the conjunctiva, and di-

lates the pupil *ad maximum*, and completely paralyzes the accommodation. Care should be taken when using it to prevent any from flowing down the tear-duct and causing toxical effects.

In examining cases of refraction under homatropin with comparatively weak solutions, the paralysis of accommodation was often of so short duration and so incomplete that changes took place while the testing was going on and before the defect could be accurately determined. With the stronger solutions, the conjunctival irritation was often so great that the patient was not at rest, and the determinations were very unsatisfactory.

In five out of my twenty cases, after paralyzing the accommodation with a four-grain solution of homatropin as far as it could, I found that on instilling a two-grain solution of duboisia the pupil became more dilated, and the paralysis of accommodation was further increased; thus showing the greater power of duboisia.

There is no doubt, however, that homatropin is a great acquisition to the ophthalmologist, as well as an advantage to our patients, in so far as its action passes off so rapidly and relieves the long and disagreeable feeling caused by atropia or duboisia, in cases where a temporary dilatation of the pupil is necessary for the purpose of correct diagnosis in troubles in the posterior chamber and fundus of the eye.

A CASE OF UNUSUAL INJURY OF THE FACE.

BY B. L. MILLIKIN, M.D.,

Resident Physician, Children's Hospital, and ex-Resident Physician, University Hospital, Philadelphia.

R. B., an Italian, æt. about 30 or 35, came under my care on July 28, 1880, suffering from a severe and unusual injury of the face.

While inspecting a coal-mine with a lamp, on the 17th of July previous, a portion of the roof of the mine fell, striking him upon the right anterior aspect of the face (so far as can be determined), and producing severe injuries. He was not unconscious when seen by another physician shortly after the accident, nor were there any symptoms of injury to the brain or its membranes, such as concussion or compression.

Upon making an examination, I found the following condition of the parts: externally there were several lacerated wounds,—one extending just above and parallel to the right eyebrow, one down the median line of the nose, and one extending from the border of the lower lip down the median line to the point of the chin,—all partially healed when seen, ten days after the injury.

There were no other evidences of any external injuries.

Upon examining the bony structures, I found more serious trouble. The inferior maxilla was fractured through the symphysis, and the fragments were freely movable; the nasal bones had sustained a compound comminuted fracture, several loose pieces having been removed by the physician first in attendance; the superior maxillæ had sustained fractures of both alveolar processes, all the teeth of either side remaining *in situ*, and it is also highly probable that there were other fractures of the bodies of the superior maxillæ, not recognizable at the time of examination.

Besides these, there was also a separation of the palatine portions of the superior maxillæ in the median line, as well as of the horizontal plates of the palate-bones, to the extent of three or four lines, and the vomer was so thoroughly disengaged from all connection with the palate-bones that it could easily be seen in the open space throughout nearly its entire length.

The soft parts of the palate were torn along the line of separation of the bones up to the junction of the hard and soft palates. Two teeth were missing in front in either jaw, and I removed a small spicula of bone from the median line of the superior maxillæ. It is also probable that there was a fracture or displacement of the pterygoid process of the sphenoid bone.

The treatment was simple and effectual. The parts were thoroughly cleansed by injecting disinfecting washes into the nasal cavity and mouth; a pasteboard cap usually employed in fractures of the inferior maxilla was made for the chin; compresses were applied over the alveolar processes of the superior maxillæ; and, the parts being in good apposition, the whole was held in place by a Barton's bandage firmly applied. Only liquid foods were allowed.

Within two weeks from the first application of the bandage the opening in the palate had entirely closed, and the alveolar processes and other fractured parts were becoming quite firm. At the expiration of four weeks the man left my charge without permission, but at that time the parts had all healed up, and the bone-fragments were solid, and all in good approximation, with the exception of the inferior maxilla, in which there was an unevenness of a line or two in the teeth of the two fragments.

This case is of interest not only on account of its rarity, but also on account of the extensive injury to the hard parts with a limited amount of injury to the soft parts. There was no evidence of any fracture of

the frontal bone along the wound near the eyebrow, nor were there any signs of injuries to the soft parts other than those enumerated. There was neither scar nor abrasion of the upper lip, over the alveolar processes, or the molar bones, beneath which the most serious injuries were inflicted.

The case is also of interest from the simplicity of the treatment employed, as well as from showing how quickly nature, when not too much interfered with, will restore serious and alarming injuries.

THE KITTANNING IRON-SPRING.

BY EDWARD T. REICHERT, M.D.,

Demonstrator of Experimental Therapeutics, University of Pennsylvania.

THE fact of the mere discovery of a new iron-spring would probably not elicit the least interest in the practitioner of medicine, since so many of these springs now abound whose medicinal waters are running to waste; but when it is found that in the water of this new spring there abound virtues far surpassing any of those of others of a similar character yet analyzed, and whose combinations and proportions of medicinal principles are something beyond precedent, it will not be amiss to give a passing and anticipatory notice of what is undoubtedly one of the most valuable of all recent acquisitions to our materia medica.

The undoubted efficiency of iron-waters in cases where none of the officinal preparations of iron could be tolerated does not appear to be so generally known to the profession as it should be, but even those few practitioners who have availed themselves of this bountiful product of nature's mysterious laboratory have used it at a disadvantage, because of the relatively small amounts of iron (often only the fraction of a grain in a gallon) contained in them, and, as a sequence, the very large proportion of water necessarily consumed in order to obtain the desired chalybeate effect. And notwithstanding the very small proportion of iron in many of these waters, and the absence of other desirable ingredients, the iron is frequently in a combination not nearly so desirable as it is in the subject of the present article, for, if Mitscherlich be correct in his deductions, the proto-salts are more readily absorbed than the sesqui-salts. It is an acknowledged fact that where iron is administered in any of the officinal forms a tendency to constipation is caused; but, owing to the large amount of salines in this water, this tendency is entirely overcome and the bowels maintained in a soluble condition, the kidneys are agreeably stimulated, and the general digestive and assimilative tone is increased.

The following analysis was made by Professor F. A. Genth, of the University of Pennsylvania, giving the contents per gallon:

	Grains.
Sulphate aluminium . .	1.52753
" ferrous oxide .	24.49271
" magnesium . .	26.84937
" calcium . . .	65.12190
" sodium . . .	8.72585
" potassium . .	.90762
Phosphate calcium . . .	.11036
Bicarb. calcium . . .	16.05445
" magnesium . .	.24629
Chloride sodium . . .	.64741
Salicylic acid	1.17201

The iron is precipitated after exposure to the air, and even after it has been bottled, but it remains in permanent solution if the water is charged with carbonic acid gas and kept tightly stoppered. The "*Kittanning Mineral-Spring Company*" (Kittanning, Armstrong county, Pa.) has furnished me with water in this condition, and I have used it in two cases with marked benefit where iron in officinal form could not be tolerated.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY HOSPITAL.

CLINICAL SERVICE OF WILLIAM GOODELL, M.D., PROFESSOR OF CLINICAL GYNÆCOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

Reported by CHARLES W. DULLES, M.D., Surgical Registrar to the University Hospital.

OVARIAN TUMOR—OVARIOTOMY.

THE patient was a colored woman aged 47 years, who had been tapped,* but in vain, before the medical class four days previous. The operation was done in a private room in the Hospital of the University of Pennsylvania, May 9, 1880, with

* See Philadelphia Medical Times for September 11, 1880.

use of the spray of carbolic acid solution, all instruments and sponges being treated also with carbolic acid solution. The abdomen was washed and wiped off with the same. The patient being rendered unconscious with ether, the first incision was made with a scalpel in the median line, about midway between the umbilicus and symphysis pubis,—a distance now, owing to stretching, of about ten inches. The incision was three inches long. As soon as the skin was cut through, a small quantity of gelatinous fluid escaped, which had come out in the line of the puncture made at the tapping, four days before, and burrowed an inch or two under the skin. There was a little bleeding from the superficial veins, which were varicose; but this soon ceased. The incision was now carried down through the peritoneum, and at once there gushed out a large quantity of serous fluid. Presently the opening was occluded by an irregular mass of colloid material, which had to be pressed aside to permit the flow of fluid from the abdomen. After some quarts had come away, this began to bring with it large diffluent masses of colloid matter, mostly of a straw color, but mingled with soft, white, caseous patches. After a little this became tinged with blood. Next, when the incision had been enlarged somewhat, there came an irregular mass, of mottled color, resembling in parts the colon, as if with very thin walls, and distended with jelly-like contents. Then a thin membrane appeared, looking like omentum, but shreddy, and resembling some gelatinous sea-weeds. This hung down over the upper and anterior part of the tumor. It had numerous enlarged veins. For the purpose of further exploration the incision was now continued, with scissors, upward and around the umbilicus. Inserting his hand, Dr. Goodell found the left ovary, but not the right. Working upward, adhesions were found of such a character that it seemed probable the tumor was attached to the mesentery. Pushing the exploration still farther, these were discovered to be simply the attachments of the colloid masses to the inner wall of a cyst which had burst, and collapsed like wet parchment. There was a great difference in different parts of the sac-wall. The left side was very thin, and had evidently burst, allowing the contents to escape into the general cavity of the abdomen. As much of the soft material as could be was now scooped out with the hand, and the remaining mass, about the size of an adult's head, lifted up so as to permit a more careful examination of its attachments.

It now became clear that the left ovary was intact, and that the tumor was a cystic tumor of the right ovary, with colloid and serous contents, which had burst and diffused itself through the abdominal cavity. It was firmly attached to the right broad ligament, and as well to the womb of that side. The uterus was normal in appearance, but dragged upward, so that its cervix was clearly above the level of the pubes. The pedicle was transfixed with strong silk (carbolized) and doubly ligated. The attachment to the broad ligament was treated in the same way, and both cut off. The remains of the tumor were now lifted out and removed. Several silk ligatures had to be applied to bleeding points on the womb. The abdominal and pelvic cavities were now sponged out. (It is to be remarked that the intestines and other abdominal viscera looked quite healthy, there being no evidence of local or general peritonitis whatever.)

A small sponge was now placed in the pelvis, and a large flat one upon the intestines, below the line of the incision, which was included in interrupted silk sutures, very long, and placed at intervals of about half an inch. When all had been placed, the edges of the incision were drawn apart, the sponge from the pelvis taken out between them, as well as that just below the wound, which had caught the little blood that oozed from the edges while the silk threads were being put in place. Everything being ready, the ends of the sutures were drawn up and tied, making a close and firm approximation of the sides of the incision. The patient was now cleaned, and the wound covered with a thick layer of antiseptic and absorbent cotton, while a binder was made to include all. She was then removed to bed.

[NOTE.—After the operation the patient reacted apparently very well, and for ten days there seemed to be a good promise of her recovery. After that time, however, she developed symptoms of peritonitis, and died on the thirteenth day after the operation. The mass removed from her abdomen at the time of operating was enormous, and estimated to weigh above seventy pounds.—REP.]

TRANSLATIONS.

CONGENITAL SCLERODERMA OF ONE-HALF OF THE FACE.—A. Pawlowski (*Cbl. f. Chir.*, 1880, p. 591; from *Wratschebnyja Wedomosti*) reports the case of a man of 26, who was brought to the clinic of Prof. Pelechin. On his right cheek could be seen an apple-sized, immovable tumor, without defined outline, merging in the surrounding skin. In the centre its consistence was firm, but it grew softer towards the periphery. The skin covering the tumor was normal in appearance, but could not be pinched up. The mouth was movable, and swallowing could be performed without difficulty, but the right cheek was absolutely immovable.

The tumor had existed from birth, and had not changed in size in the patient's recollection. It was sensitive to cold, exposure causing it to become red and swollen. On closer examination the facial nerve of the right side, except the twigs going to the eyelids, appeared to be perfectly paralyzed. The sense of touch, in comparison with the left side, was decidedly diminished. Electric conduction, on the other hand, seemed heightened. An elliptic piece was cut out of the middle of the tumor, and it was subjected to firm pressure alternated with the application of the galvanic current. In a short time the skin began to soften, and before long could be picked up in folds.

Microscopic examination of the affected skin showed the epidermis and rete increased in thickness, the ducts of the sweat-glands enlarged and tortuous. There was cell-proliferation in the sweat-glands themselves and in the sebaceous glands as well. Hæmatoxylin staining showed the whole thickness of the cutis, the reticular layer, and particularly the subcutaneous connective tissue, filled with vessels of various size. The adventitia of the vessels was infiltrated with white blood-corpuscles; the same infiltration could be observed in various localities in the tissues, sometimes in groups, sometimes in distinct series. They were more plentiful in the rete. The pars reticularis was almost entirely transformed into a compact mass of connective tissue; the hairs were short, brittle, and increased in number. The subcutaneous adipose tissue was wanting in most specimens; in some it took the form of small strips of fat cells compressed by bands of connective tissue, or of small masses of fat surrounded by firm connective tissue. In addition to the history of this case, Pawlowski gives a full bibliography of the subject, and points out the novelty of his own successful treatment.

REMOVAL OF THE VAGUS WITH A CERVICAL TUMOR—CURE.—Professor Lücke (*Cbl. f. Chir.*, 1880, No. 36) reports the following case. A woman whose sister had died with lymphoma malignum of the neck applied for relief from a tumor, oval in shape, rather hard, movable, and situated in the right submaxillary region. It was removed without difficulty, and the wound healed by first intention. On examination of the tumor by Professor Recklinghausen, it was pronounced a hyaline cancroid, connected with but not implicating the salivary gland.

About two years later the patient again applied for treatment, the disease having returned in the cicatrix and also under the right sterno-mastoid. There was no functional disturbance; the patient's health was fair. The smaller tumor in the scar was removed with some difficulty, being found to lie more deeply than appeared from its growth externally. There was much venous hemorrhage. The new, larger tumor was laid bare by an incision along the edge of the muscle, which was closely connected with it. On cutting this above and below, the carotid was found separable from the tumor, but the latter had grown completely around the jugular vein and the vagus. The vein was close to the upper border of the clavicle and above the tumor, and the piece was then removed with the tumor and with a portion of the vagus twelve centimetres (four inches) in length.

No noteworthy alteration in respiration and pulse occurred at the moment of section. The wounds healed rapidly. Five months later the patient showed easily-excited but otherwise normal respiration, the right arm was slightly weaker than the left, and the shoulder could be raised with difficulty. The right side of the neck was flattened; the pulsations of the carotid could be felt along the whole course of the scar. Pressure on the latter, particularly at the upper and lower stump of the muscle, aroused fits of coughing. There was suspicious hardness in the submaxillary scar, but no positive return of the growth. The right side of the face, particularly about the cheeks, showed a hy-

pertrophic condition, most likely the result of the ligature and removal of the common jugular vein.

Varicocele and its Treatment.—C. Nebler (*Inaug. Diss.*, Breslau, 1880; *Cbl. f. Chir.*, 1880, p. 635) urges the radical operation,—double ligature after laying open and excision of a section of the venous plexus,—with antiseptic precautions. He says this is absolutely without relapse and usually harmless. His views are based on five cases operated upon by Fischer. Nebler also concludes that atrophy of the testicle, which was observed as the result of two operations in Halle and once by Miflet, is not necessarily the result of the operation, but of the simultaneous wounding and ligature of arteries. Experiments on animals are brought forward by Nebler in support of this view. He regards the older operations as frequently dangerous.

Tuberculosis and Pregnancy.—Gaulard (*Thèse de Paris, Le Progrès Méd.*, 1880, p. 670) says that pregnant women are far from enjoying that immunity from acute and chronic disease which used to be supposed. Pregnancy exercises anything but a salutary influence on the course of tuberculosis. The puerperal condition aggravates phthisis, as does nursing. Gaulard brings forward a large number of cases in support of this view. In one series of thirty-two cases, phthisis existed before pregnancy; the aggravation of the disease was, so to speak, constant. In a second series, tuberculosis appeared at a more or less advanced stage of pregnancy, and became worse and worse until its termination. Finally, in a third series of cases, phthisis did not seem to show itself until a period more or less prolonged after accouchement. It seems to Dr. Gaulard that in these last cases the puerperal condition exercised considerable influence on the appearance of the disease. On the whole, the influence of pregnancy, as shown by Gaulard's statistics, is unfavorable: in pregnant women phthisis runs a more rapid course than in other women.

Treatment of Cystitis.—Diday (*La France Méd.*, 1880, p. 523) recommends patients suffering with this disease to drink daily a large glass of flaxseed tea mixed with orgeat or other flavor, or with some mineral water. A stimulating plaster twice the size of the palm is to be placed over the kidneys, and if necessary retained in position until it produces an eruption. The patient should take great care to resist the inclination to pass the last drops of urine. This is very important, and exercises an immediate happy influence on the tenesmus and the exudation of blood. In addition, a pint of an infusion containing the following powder is to be taken twice daily: ℞ Folii hyoscyami, gr. xii; sacch. alb., gr. ii.—M. A slight narcotic effect is produced by this infusion, which is favored by inunctions in the perineum with belladonna ointment, or by rectal suppositories containing one and a half to three grains of extract of belladonna. If the pain persists, the narcotics can be increased to a toxic degree, carefully watching their effect. During the morning the patient drinks every half-hour a tablespoonful of an infusion of forty-five grains of hyoscyamus in three ounces of water. In a few hours relief is almost always obtained. The medicine may be begun again after a few days if the trouble returns. Ice is indicated in anal tenesmus and enlargement of the prostate. For the prevention of ammoniacal urine the following prescription is recommended:

℞ Acid. benzoic., gr. xv ad xl;
Glycerinæ, f℥i ad ℥iss;
Syrupi acaciæ, f℥v.—M.

Sig. Half a teaspoonful to a teaspoonful daily.

Treatment of Fissure of the Anus.—In an unusually painful case of this character Dr. Glénerau (*Bull. Gén. de Thérap.*, vol. ii., 1880, p. 269) used the following means of relief. The patient took about a drachm of calcined magnesia in syrup every evening before retiring. In the morning she was seated upon a commode containing a boiling-hot decoction of belladonna leaves kept hot by fresh additions of the same, and the vapor confined by a wrap around the seat and body of the patient. After a few minutes efforts at defecation were made, which at first were very painful. When the pain began to lessen, the efforts were again made, and the pain became less and less. After the stool was finally passed, a few minutes more were spent over the belladonna vapor, and then the following suppository was placed in the rectum:

℞ Ol. theobromæ, ℥ijss;
Ext. belladonnæ, gr. iij;
Ol. amyg. dulcis, q. s.—M.

The ointment was smeared upon a wisp of lint, and this formed the suppository, which

was renewed if it fell out during the day, and was changed every morning after the fumigation. After eight days of this treatment the patient was much better: the magnesia was stopped on the tenth day, the suppository on the fourteenth, and the fumigation at the end of the third week, though the patient was recommended to use the latter from time to time.

Symmetrical Neuralgia in Diabetes.—M. Worms (*La France Méd.*, 1880, p. 627) thinks that no new fact which may aid in the rational classification of the different varieties of diabetes ought to be neglected. For this reason, he communicates notes of two cases of symmetrical neuralgia in the sciatic and in the inferior dental nerves occurring in the course of diabetes. This variety of neuralgia has not heretofore been described. M. Worms's conclusions from these cases are as follows:

1. There is a peculiar form of neuralgia which may occur in connection with diabetes, and which is characterized by affecting two symmetrical branches of the same nerve.

2. Thus far this form of neuralgia has been observed only in the dental and sciatic nerves.

3. Diabetic neuralgia appears to be much more painful than ordinary neuralgia.

4. It does not yield to the ordinary treatment of neuralgia (quinia, morphia, bromides); it becomes aggravated *pari passu* with the progress of the diabetes.

M. Worms classes this form of neuralgia with the diathetic varieties observed in gouty and chlorotic persons and in lead-poisoning. He leaves undetermined the question as to the existence of any perceptible lesion of the nerves or neurilemma.

Sub-Ungual Sarcoma of the Left Middle Finger.—Kraske (*Cbl. f. Chir.*, 1880, No. 38) gives the following instance of this rare form of disease. A woman of forty-two had felt a painful sensation under the nail of the left middle finger for twelve years, increased on the least pressure. The trouble was attributed to a severe squeeze. Repeated scraping of the nail over the painful spot gave only temporary relief. When first seen by Kraske, July 28, 1880, a linseed-sized blue spot could be seen under the nail, pressure upon which caused the most acute pain. The nail showed otherwise nothing abnormal, but, for reasons to be given, a sub-ungual tumor was diagnosticated, and the finger-tip was amputated without the removal of the phalanx and with a volar flap. The wound healed by first intention, and the patient was discharged a few days later quite free from pain. Examination (the details of which are given in the original) showed the tumor to be an angio-sarcoma. The diagnostic point upon which Kraske depended in deciding on the nature of the tumor was its peculiar suggillation-like appearance, an aspect which has been noted by Volkmann in a similar case, terminating fatally, however, by general sarcomatosis. This appearance is caused by congestion of the blood-vessels around the tumor, which is compressed between the nail and the phalanx.

Tuberculous Ulcers of the Tongue.—Reimann (*Inaug. Diss.*, Breslau, 1880; *Cbl. f. Chir.*, 1880, p. 633) says that this affection was first described by Portal, in 1804, and has since attracted increasing attention. It shows itself in the form of tumor and ulcer (probably stages of the same process), solitary or multiple. The latter form appears to be the rarer, as among eight cases collected by Reimann only one was in the form of an ulcer. The point of election appears to be the tip of the tongue and its border. The affection is usually secondary to tuberculosis of the lung and intestine. Since it is frequently painless, the differential diagnosis between this affection and syphilis or carcinoma is sometimes difficult, at least when the disease of the internal organs is not perceptible. The treatment of tuberculous ulcers of the tongue, when solitary, is usually excision. In most cases this is successful; but occasionally the wound made becomes itself a tuberculous ulcer.

Treatment of Exophthalmic Goitre by Duboisin.—Dr. Dujardin-Beaumetz (*La France Méd.*, 1880, p. 571) has substituted duboisin in hypodermic injections for atropin in the treatment of cardio-thyroid exophthalmos. In two cases where he has employed this treatment he has obtained great diminution of the palpitations and of the vascular throbbing. He has also observed a ready accumulation of doses, although he has injected only very small quantities of the drug,—a quarter milligramme to a half milligramme at the most. At the end of a few days unquestionable signs of poisoning showed themselves, analogous to those brought about by bel-

ladonna. The solution used for the injections was composed of neutral sulphate of duboisin one centigramme, distilled water twenty grammes. Each syringe of one centimetre cube contained a half milligramme of the salt of duboisin.

Differential Diagnosis between Hepatic and Nephritic Colic.—In an excellent article pointing out the characteristic seat and nature of the pain felt in each of these diseases, Dr. Cornillon (*Le Progrès Médical*, 1880, p. 661) concludes as follows: "There is not the least resemblance between the painful points in hepatic colic and those of nephritic colic. In the first place, the latter are incomparably the most severe. In addition, the first are seated at the base of the thorax and above that point, as in the epigastric, cystic, dorsal, and scapular regions, while the pains in nephritic colic are referred to the inferior segment of the body,—the renal, lumbar, inguinal, and testicular regions. In doubtful cases the exact determination of their respective position is an excellent point in the differential diagnosis."

Internal Erysipelas; Erysipelatous Pneumonia; Consecutive Erysipelas of the Face.—Cuffer (*Cbl. f. Chir.*, 1880, p. 623; from *La France Méd.*) describes a case where fever, vomiting, dyspnœa, and pain in the right lower lobe of the lungs, with apparent pneumonic infiltration of that lobe, was observed eight days before admission to the hospital. Characteristic sputa were not observed,—which threw doubt on the diagnosis. On the third day after admission to the hospital, facial erysipelas, beginning first at the tip of the nose, developed without additional fever. On questioning the patient, it was found that he had shortly before lain in the bed of an erysipelas patient. Cuffer concludes that the disease attacked the lungs first, spreading thence to the trachea, larynx, pharynx, and so to the face.

Heart-Disease and Pregnancy.—Prof. Peter (Porak, *Thèse de Paris*, *Le Progrès Méd.*, 1880, p. 671) forbids marriage to a woman with cardiac disease. If she is married, he forbids pregnancy; if pregnant, he forbids suckling. When pregnancy and heart-disease coexist, Porak advises waiting unless some symptoms arise. Should trouble of the heart supervene on the approach of labor, this is to be hastened and terminated rapidly. If the woman's life is threatened, earlier premature labor, or even abortion, should be induced.

Pruritus Vulvæ.—According to Martineau (*Le Progrès Médical*, 1880, p. 530) pruritus vulvæ may be due to general causes, such as glycosuria, pregnancy, and nervous perturbation, or it may originate in mere local disorders, as intestinal worms (oxyuris), pediculi, tinea tonsurans, vesical calculi, vegetations or polypi of the urethra, or vulvitis. The general condition of the patient should be very closely looked after, and appropriate remedies should be applied to remove the remote cause of the trouble, whatever that may be found to be.

In the acute stage of pruritus accompanying vulvitis, emollient applications are, of course, indicated. Starch poultices (not linseed, for this decomposes too easily), lotions of infusion of belladonna, aconite, or poppy-heads, or of a weak solution of bromide of potassium or of chloral (three grains to the ounce), may be used. They should be hot rather than cold. Washes of corrosive sublimate of one-per-cent. strength may be employed when the stage of acute inflammation is passed.

Fifty parts of perfectly neutral glycerole of starch, containing one part of the following substances, tannin, calomel, extract of belladonna, or oil of cade, according to circumstances, may be used with advantage. Now and then light cauterizations with nitrate of silver prove advantageous. Révillout has occasionally found that the insertion of slices of citron between the vulva will allay the itching. In chronic cases Dr. Guéneau de Mussy anoints the vulva night and morning with the following:

℞ Glycerol. amyli, ℥j;
Potassii bromidi,
Bismuthi subnit., āā gr. xxv;
Hydrarg. chlor. mite, gr. x;
Ext. belladonnæ, gr. v.—M.

The vulva are to be washed with a dilute solution of borax containing a little emollient, as starch.

Delioux de Savignac follows the lotion just mentioned with a powder:

℞ Pulv. lycopodii, ℥j;
" bismuthi subnit., ℥iss;
" radicis belladonnæ, ℥ss.—M.

In very rebellious cases, hip-baths, each containing two to three drachms of corrosive sublimate, first dissolved in dilute alcohol, may be employed.

INSANITY LAWS.

THE subject of the proper legal enactments for the control and protection of the insane has been of recent times the source of so much bitter writing that we hesitate somewhat in stirring it up. There is one point, however, concerning which action might well be taken at the present time. In several, if not most, of our Eastern States the law is such that in an acute case of mania, in suicide, melancholia, etc., very serious suffering might result, and no doubt has in some instances resulted. In this State the physicians have to make affidavit before a magistrate as to the asserted lunacy of the patient; in Massachusetts a magistrate has to endorse the commitment; in New York some legal officer—the County Judge, we believe—has finally to sign the papers. We believe that the law in New York allows the patient to be put in the asylum and retained there four days awaiting the proper papers; and certainly such is the custom in some or all of the State institutions. This obviates the difficulty of which we are writing; but no such proviso exists in our Pennsylvania law.

Suppose the acute maniac becomes violent on a Saturday evening in this State, nothing can be done legally until Monday; or suppose, under the Massachusetts law, the medical certificate in a similar case has been signed, the magistrate is not to be found, Sunday intervenes, and the requisite formalities are not completed until Monday. Meanwhile, what of the unfortunate patient? What is to be done with him? If poor, he is given over to the care of the police, who are just as liable to handle a lunatic with violence as they are to abuse an excited inebriate. Moreover, the lunatic, who should at once be sent to an asylum, is confined in the dreary cell of jail or station-house until he can be received into a hospital. Such confinement and such treatment may convert an acute into an incurable mania. If the insane man be rich, he is kept at home, to his own detriment and danger, and to the great distress, and perhaps actual peril, of his family.

At a recent meeting of the Councillors of the Massachusetts State Medical Society the president was requested, by a unanimous vote, to appoint a committee with instructions to consider the necessity of a law that will safely and carefully provide for the insane during the interval that now may elapse between the recognition of the madness and the commitment to the asylum. The need of such provision is not a mere fancy. Some few weeks since, we saw a lunatic in one of our large hotels, just arrived from Cuba, his father almost as distraught as himself with anxiety lest harm should result before he got his son safely lodged in an institution. It being late in the day, only with the greatest difficulty were the necessary formalities accomplished.

The necessary modification of the law might be very simple. Let it be allowed for two physicians to give an order which should give legal power for three or four days to the authorities of institutions to restrain lunatics until time was afforded for the same physicians to make the necessary affidavits, and the desired end would be reached. The requirements of our Pennsylvania statutes are, however, very foolish. The doctor who would falsely sign a certificate of insanity would make affidavit to the same. It would save expense and trouble if only the simple signatures of the physicians were required, and would afford just as much protection against the incarceration of the sane.

THE number of medical students in Philadelphia this year is about as large as in previous years. The inauguration of the preliminary examination has had a very perceptible effect upon the first-year medical class at the University, probably frightening off about twenty per cent. of the men. It has, on the other hand, attracted some who would not otherwise have presented themselves. The character of the University class is shown by the number of Masters and Bachelors of Arts and Sciences, these constituting over thirty per cent. of the class. The total class of the University is something over three hundred and fifty men. A curious feature is the large number of second- and third-year men: thus, there are more second-year men than there were first-year men offering themselves for examination last spring, the gains from other institutions more than compensating the rejections of the spring examinations, losses from sickness, etc., etc. The Jefferson class is stated to be larger than last year, numbering in all about five hundred and fifty matriculates. The class of the Women's Medical College is also larger than last year.

LEADING ARTICLES.

WHAT CAN MINNESOTA DO FOR CONSUMPTIVES?

THE antiquarian who shall examine our climatological literature some centuries hence, if he be an inductive philosopher and acquainted with Lucan, will probably take out his pencil and record, as his conclusion, *Jupiter est quodcunque vides, et quocunque moveris;* for, whether Cowes, or Mentone, or Cairo, in the Old World, or St. Augustine, or St. Paul, or Denver, in the New, be the theme, good and sufficient reasons will be found to be adduced in each instance to establish the proposition that each particular spot is the world's sanitarium, and that it possesses certain undeniable advantages over its rivals.

The unfortunate practice of extravagant laudation goes often hand in hand with failure to discriminate not only between different cases of the same malady, but even between different diseases; and so the fact that a given locality has acquired a reputation as a health-resort is regarded as a valid reason for recommending a trial of its virtues to those whose ailments have failed to yield to other treatment, with but little regard as to what may be their nature. And thus a resort possessed of material advantages for cases judiciously selected falls undeservedly into disrepute because it does not prove to be the grand catholicon for human ills.

In common with other sanitaria, Minnesota has suffered from this system of what may be termed miscellaneous recommendation; and the following statements are offered in the hope that the presentation of a few well-ascertained facts, as to what may be reasonably expected from its climate in cases of phthisis and what may not, will be of some assistance in enabling professional men to form an intelligent opinion when a visit to that State is contemplated for the relief of consumption.

Those who are familiar with the climate of Minnesota will pardon the unavoidable repetition of statements which have been already frequently made.

The elevation of Minnesota above tide-water ranges from eight hundred to one thousand feet. Its soil is composed almost entirely of drift deposits of three varieties, —blue clay, stratified clay, and gravel and sand; and these are covered to the depth of one or two feet by a rich silicious loam. The thermometric record for the last four years is as follows, the figures in all the tables indicating the annual mean:

	Maximum.	Minimum.	Difference.
1879 . .	71.7°	14.2°	57.5°
1878 . .	71.8°	23.7°	48.1°
1877 . .	69.9°	20.4°	49.5°
1876 . .	68.5°	14.5°	54.0°

The following table represents the barometrical observations for the same period:

	Highest.	Lowest.	Difference.
1879 . .	30.437	29.397	1.041
1878 . .	30.315	29.353	0.962
1877 . .	30.372	29.444	0.928
1876 . .	30.444	29.376	1.068

The mean relative humidity for 1879 was 65.3; for 1878, 67.7.

The amount of rain and melted snow is shown in the next table in inches:

1879	32.39
1878	22.78
1877	28.81
1876	23.67

The prevailing winds in summer are from the southeast; they are, however, more variable at this season than in the autumn or winter, when north and northwest winds predominate. The latter are dry in Minnesota, although cold and damp in the more eastern States, because of the different conditions under which they reach the two sections,—in the one case coming over the great lakes and Hudson's Bay, and in the other over a surface of land equal in area to the United States east of the Mississippi.

The persistent northeast storms of the Eastern States are infrequent in Minnesota. During 1875 the wind blew from that quarter on but ten days, in 1874 on twelve, and in 1873 on sixteen, and in no instance during more than two consecutive days.

The principal conditions, then, which have to do with climate are as follows: considerable elevation, a soil admitting of rapid absorption, low mean temperature, somewhat low barometric pressure, and winds which, especially upon the exposed prairies, attain a high rate of speed, but bring with them very little moisture,—in other words, a stimulating climate; and, speaking in general terms, under such circumstances we should expect to find that pathological processes of which an active hyperæmia and a tendency to rapid extension are distinguishing features will fail to be arrested and might even be aggravated. On the other hand, it will be reasonable to look for improvement in those cases in which the progress of the disease is slow, and indurated walls are opposed as a more or less effectual barrier between the diseased portions of lung and the unaffected pulmonary tissue. The stimulating effect of the climate, prejudicial in the one case, is helpful in the other.

As the object of this article is not to offer hypotheses, but simply to record facts, the *rationale* of the effect of low temperature and of a climate such as is under consideration will not be dwelt upon. The known resultants are a greater demand for oxygen by the various tissues, a consequent increased activity of the respiratory centres and more complete expansion of the lungs, with quickened appetite and improved nutrition. The facts observed during upwards of thirty years in Minnesota are such as to justify these conclusions. To speak broadly, the experience of physicians indicates that patients to whom the conditions in question are most suitable are those in the incipient and, if possible, in the pretubercular stage of consumption. Next to these, as likely to be benefited, is the class to which reference has been made, in whom the form of the disease is essentially chronic; nor is hæmoptysis in either class a contra-indication to a trial of the climate. It seems almost superfluous to say that in the case of the latter as well as of the former class the earlier relief be sought the better; but even when recovery is out of the question, instances are numerous of persons who have come to Minnesota with an expectation of life amounting at most to a few weeks, but who have acquired a reasonable degree of vigor, and have been in the active discharge of professional, official, or mercantile duties for periods varying from five years to ten, and even longer; who are not well, and who will eventually yield to the disease fastened upon them, but whose lives have been greatly prolonged, and the sum of whose comfort and usefulness has been greatly increased.

Dr. Lincoln, of Wabasha, Minn., says, in writing of the State as a health-resort, "I would not have an atmosphere too dry nor too damp. I would have the temperature variable, so as to induce a necessity and inclination to exercise, that digestion and nutrition of all the tissues may be promoted. I would not place myself at an altitude where I must breathe thirty times a minute to inhale as much oxygen as I ought to get in a respiration of twenty times a minute. I would look for a country where I could remain in the open air a part of every day. I would live in a house where an equal temperature could be maintained, and where good ventilation was active night and day. I do not believe it best for a patient with advanced phthisis to leave a comfortable house, be that where it may; but for the advantage of persons in the incipient stage of the disease the State of Minnesota has, in a great degree, the favorable conditions herein mentioned."

As to the length of time requisite for the relief of consumption, it may be said that in many cases permanent residence is

a *sine qua non*, while in almost every instance only a prolonged stay can be relied upon for recovery or even for decided improvement. It has happened many times that apparent restoration has begotten a false sense of security, and return to a former home has rekindled the disease and led to a speedily fatal issue.

It is better, for obvious reasons, that invalids should come to Minnesota in the summer or early autumn rather than late in the latter season or in the winter,—a precaution often disregarded. As regards persons who have derived or who may derive the minimum of benefit from a trial of the climate, a word should be said.

It has been remarked that phthisis of an acute type is unlikely to be benefited, and that in other cases the prospect of relief is in direct proportion to the period at which relief is sought. In addition to this, the climate of Minnesota tends to the development of catarrhal affections of the respiratory tract, and catarrhal phthisis, especially when the bronchial apparatus is extensively implicated, must be placed in the category of varieties least susceptible of improvement.

No distinction is made in these remarks between pneumonic and tubercular phthisis. While the prospect of ultimate recovery is, of course, greater in the former, the latter may at least be benefited, subject to the conditions which have been mentioned.

The following statistics are offered that comparison may be made with corresponding returns from other localities. It should be borne in mind that a considerable number of persons come to Minnesota with the disease so fully developed that relief is impossible, and that not a few of those whose death is attributed to consumption are in reality victims of senile bronchitis. The percentage of deaths from phthisis in Minnesota was, in

1879	9.9
1878	10.5
1877	11.1
1876	10.5

GLYCEROLE OF THYMOL.—The formula is—

℞ Thymol, gr. xx;
Glycerinæ,
Alcoholis, āā f℥i;
Aquæ destillat. ad Oj.—M.

Useful in pityriasis, and, when diluted, as an effective antiseptic mouth-wash.

CORRESPONDENCE.

LONDON LETTER.

THE present object of interest here is the opening of the medical schools and the commencement of another winter session, fraught with the hopes of so many first-year's men. How many of these ardent youths will fall out of the ranks before they take a qualification, how many will retire from the profession after having worn harness for some years, it is not possible to say. But the gift of prophecy would, it is to be feared, tell of a very heavy percentage of both. How many will fall victims to their warfare with disease in all its forms, also may not be told; but that a distinct number will so perish is certain. The profession furnishes non-combatant officers to the services; but, non-combatant or not, a considerable proportion contrive somehow to get killed, instead of dying in their beds,—as surely a non-combatant officer, if only for the sake of example, ought to do. Quite certain it is, too, that if a surgeon is fighting instead of minding his own business proper, he deserves to be—well, no, not killed, but wounded; an unskilled combatant will probably do the fighting just as well; but if the trained surgeon gets *hors de combat* it is not easy to supply his place.

Of course, with the opening of the session came the various addresses, when each lecturer poured out a sample of what he had got within him; and, it is needless to say, the samples varied. Following the lead of Henry Power and Michael Foster, Prof. Burdon Sanderson shook his fist defiantly at the time the student has to spend in acquiring information which he is not expected even to retain, as a rule, after he has left the examination-table. He earnestly impressed on his hearers the consideration that "the one thing needful" in medical education was neither the acquirement of scientific knowledge nor the preparation for examinations, but preparation for the responsibilities of practice; and with that view he gave an account of the system of instruction carried on in University College Hospital, in which the student was led, by successive practical lessons at the bedside, to observe and discriminate the signs of disease, to form a conclusion from them as to its nature, and, finally, to act for himself for the relief of the sufferer. "Every student," he said, "finds that from the moment that, having completed his studies in human anatomy and physiology, he becomes engaged in the wards of the hospital, he has very little time for other kinds of work, and that residue of time is subjected to still further diminution by the yearly increasing requirements of the examining boards, so that the final remainder of leisure available for real work outside the hospital is extremely small. The precious years which immediately precede a man's

entry into professional duty are far too valuable to be wasted in learning anything that he does not intend to retain." Yes, it is high time protest after protest should be issued against the "lumber-portion" of medical study,—the impedimenta of the student's onward march. One of the professor's most promising present pupils is, to my personal knowledge, getting up early in the mornings, when his memory is fresh, to—what?—to learn the ligaments! Of course it is very well for a practitioner to know the ligaments as an accomplishment, but not as a serious preparation for his conflict with disease, occupying a very distinct portion of those "precious years." Granting that it is pleasant to see a practitioner so well informed that he even remembers about his ligaments, still this knowledge is scarcely of that tremendous importance that it is needful to know it so thoroughly as to be able to carry it about with him. It may be questioned how far accurate remembrance of the ligaments will be of any avail to a man even when treating a sprain. And yet any other opportunity for making such knowledge useful can rarely come a medical man's way,—unless it be giving evidence at a coroner's inquest in a case of broken neck, when he might impress a jury with his learning by talking of the atlo-axoid ligaments; and then perhaps he would achieve the feat just as well by looking up the matter in Gray—just as I have done—as if he had carried the name in his head, ousting more useful information. However, it is good to see men who are not in practice, like Sanderson and Foster, insisting so firmly that men shall be educated to be of use to their fellow-beings in practice, whatever else they may not be.

Dr. Waters, in his address to the Liverpool School, pursued the topic thus: "The great object for which you come here is to learn how to recognize and treat disease,—to learn how to be of practical use in the alleviation of human suffering. The public estimate our services, and will honor and reward us, in proportion as we are able to treat successfully their ailments. They do not stop to inquire how far we are skilled anatomists or able physiologists,—how far we are good chemists or botanists,—but how far we can, by the application of remedial measures, cure their diseases; and therefore, although the sciences connected with medicine are of the highest importance, a knowledge of them alone will not make a physician or a surgeon." It is positively refreshing to find that once more medical teachers are recognizing the fact that the public would like to have something for their money; that what they want is a man who can benefit them in return for the money they pay,—in fact, "value received." This is a healthy reaction against the doctrine recently taught insidiously, if not formally promulgated, that it was first of all requisite that a medical man should be highly educated, familiar with the collateral studies of medicine, well informed in society, learned in the causation of disease, skilled in its detection, prophetic almost in his diagnosis, but impotent, or nearly so, as a therapeutist,—professing not to believe in drugs. The impertinence of this last was only equalled by the dishonesty underlying it. If the man who "disbelieves" in drugs arrived at his conclusion after long, patient, unbiassed trial of them, then his conclusions would be entitled to every respect. But when the assertion comes from lips which speak from the stand-point of the dead-house, from the physical examination in the hospital wards, when the tired teacher almost forgot to prescribe, then it carries no weight of conviction with it: it is undisguised impertinence which ought to be birched. When a patient comes to one in trusting confidence, placing health and life in our hands, and with them the prospects of his wife and children, surely in return a medical man with a spark of manly feeling or true self-respect will meet that trust as a man ought to do,—viz., by the fulness of knowledge. Ignorance which can be removed by pains is nearly as execrable and morally detestable as malice. To let a patient die for the want of knowledge which can be acquired if the effort were made properly, is nearly as wicked as to kill him purposely. To slay a patient by ordering him chloral when the respiration is failing,—no uncommon event, I regret to say,—because the prescriber is ignorant of the effects of chloral upon the respiratory centres, differs little from wilful murder. It is a pity that some of our teachers do not look at the matter of therapeutics from the stand-point of the day of judgment. I venture to think that, if they did, a number would reconsider their therapeutic belief.

Dr. H. Donkin, at Westminster Hospital, has looked at the subject in this light. He says of the doctor, "He, more than any, has to exercise, in the complexity of his relations, that fine taste, the heritage of the ages, which enables him to distinguish between right and wrong, and has constantly, while regarding his own necessary self-interest, to keep in view his bounden duty to his fellow-men. The doctor alone is paid for doing what all right-minded men would freely do for their fellows,—all that is in their power." Certainly; but do all of them do "all in their power," when they allow themselves to be grossly ignorant of the advances in therapeutics? Yes, and he puts forward ably a view too little entertained,—namely, the desirability of being personally familiar with some of the work done in the past; of knowing how the investigator worked, and registered his work, and put it on record; the bald facts of which find their way into text-books and are part of the permanent stock knowledge of the profession. He says, "Day after day utters new books, though not always new knowledge; and the work of those who have gone is either for-

gotten or reproduced, not always even then improved. We should perchance be spared some of the immoderate plague of crude, superfluous medical writing, were men more given to the study even of ancient works, and of those of the great departed moderns in their original form. And not only would literature be the gainer, but sound clinical knowledge would more abundantly flourish, were the original writings of such men as Cullen, and of Bright in later days, and of some, too, whom we are proud to have among us now, to occupy more of our student time. Practical medicine would scarcely be the loser were a colder welcome given to the appearance of compendiums and bald abstracts of others' works, and a less price offered for the committal to memory of lifeless catalogues of facts,—a labor through which it seems before all things necessary that he who would be highly examined must pass." The study of the work, well known and generally recognized as valuable, of some past writer in his own words would be a good addition to the present course of study, as regards the education and edification of the medical student's mind and his preparation to observe and think for himself, which all men ought to do, and a few do. He goes on to another subject: "It is the ignorance or the forgetfulness of the fact that many very palpable maladies can be traced no farther back in the chain of causation than to a link distinctly mental—however subtly, as we may allow, some physical change may underlie it—that leads so many of us, at the present day, to commit the gravest errors of opinion and practice. Leaving out of sight some diseases well known and trenchantly marked out by clear-cut symptoms, which can be referred with the greatest probability to an origin other than confessedly physical, there are many less definite but troublous ailments which defy all treatment, while their emotional cause remains undiscovered by the ignorance or indolent incredulity of the doctor. On the one hand, such maladies are derided as shams, or, on the other, are put down, to the infinite hurt of the patient, to some condition existing only in the mind of the physician, to cover his escape from the unpleasant necessity of confessing his ignorance. I cannot here expand this subject; but I have known cases of patients who suffered from wasting and many symptoms of failing health sent airily away, after a short interview with a doctor, to a distant country with the false brand of 'threatening consumption' upon them, to the great damage of their lives' work and prospects, when their every ailment was due to a mental trouble, which a little insight and sympathy would have induced them to reveal, and which, by such revelation, might have been largely, if not wholly, dispelled." Here is another charge brought against sundry members of the profession,—viz., that they possess not the requisite tact and knowledge to find out what is the matter with their patients, and send away these patients to foreign lands, to the detriment of all their worldly interests, when really they ought to send them away telling them to consult some one who may possess more insight. No; it is easier to send them away abroad and trust to time. If the patient gets well, then the credit of a cure is assumed; if the patient becomes really ill, then the opinion is confirmed. It is a curious suggestive fact that of the physicians who have the strongest partiality for sending their patients abroad, a large portion do not command the intellectual respect of their fellow-men in the profession, or are avowedly sceptical as to the efficacy of drugs. It is commonly enough said, "Oh, yes, he sends his patients abroad when either he does not know what is the matter with them or does not know what to do for them." And it is to be feared that this is not always mere scandal. These refuges of "ignorance or indolent credulity" are getting exposed one after another, and do not have the effect of increasing the confidence of the public in the profession.

In connection with this subject lies the cognate question of the morality, or rather the want of it, displayed by some of the resident medical men in health-resorts. Rather more than a year ago I saw the daughter of a doctor who had some consolidation of the apex of one lung, for which she had been sent to a Swiss valley for the preceding winter. She had enjoyed the foreign stay, for her mother, the younger children of the family, and the governess had gone with her. But this was a most serious expense. I asked, Had she had any medical treatment? The answer was, "None." So I prescribed a pill of arsenic and iron to be taken steadily during the ensuing winter, in addition to the residence abroad. She returned, and the doctor then, without any consultation with me whatever, stopped the pills. The girl came back in spring so ill that her mother at once put her back on the pills, under which treatment she has made the most satisfactory progress. Now, this means either culpable ignorance and presumption, or unspeakable villany. Words are unequal to express my detestation of such grasping greed, such low, shallow cunning. If this is to be the way that health-resorts have to be manipulated and engineered, then the practices of a Wall Street ring are respectable by comparison. But of course such transparent rascality defeats its own ends. This winter that patient is going to remain in England and take the pills, in preference to another experience of the climate, the still air, and the many hours of cloudless sky of that famous health-resort.

Dr. Donkin goes on to say, "The quack is not yet gone from among us; nay, rather, he

lives and he flourishes, protean in form and chameleon in hue. These are they who turn aside from the path of that duty which their profession, in its true and highest meaning, involves, at the lure of those rewards which fall alike to the unjust and the just, if indeed they come not to the first of these in the richest profusion. Trading, and only trading, in the name of science and humanity, they desecrate the one and make sport of the other for their own ignoble ends, using the screen of distorted knowledge to hide their base but too successful endeavors to build a fortune out of the ignorance and the superstition of the public whom they rob." In his concluding sentence he says, "If I have seemed to over-wantonly expose some plague-spots in our midst, or speak too strongly of our sins, I can say no more in extenuation than that I have felt as strongly."

Perhaps it will be a matter for surprise for some readers to learn that this lecture has appeared *in extenso* in the columns of the *British Medical Journal;* yet this is the fact. That periodical is waking up a bit from its lethargy of self-satisfaction. Listen. "How weary, flat, stale, and unprofitable is an ordinary meeting of a Branch Association! How tedious the orator! how listless the audience! how dull the debaters! No wonder the attendance is small; that Smith is too busy to be present, and that Brown instructs his wife to send an urgent message for him when the pipes and coffee are coming to an end." Such is the tenor of a letter on "The General Practitioner" in the number for October 16. It goes on, "The time has come for the settlement of the question whether the family doctor is to be a physician or a tradesman with a medical qualification. Can he dare to rest his claims for daily bread and social recognition on his knowledge and skill in medicine, or must he still be a compounder of drugs and an apt manipulator of bottles and sealing-wax?" Perhaps those very men whom the editor led off into indignation at some remarks of mine a year ago will read this letter and give it their earnest attention. Possibly an improvement is feasible (however desirable it may be is not the question) in some of those elements of the profession who degrade it in public estimation. The present position of the struggle at Guy's Hospital is not likely to elevate us in the eyes of the public, who are watching it with eager interest.

J. MILNER FOTHERGILL.

TO PRESERVE THE STRENGTH OF MAGENDIE'S SOLUTION.—The following is the formula of Dr. H. M. Keyes, he having called attention to its successful employment in Roosevelt Hospital some years ago:

℞ Morph. sulph., gr. cclvj;
Acid. salicylic., gr. viij;
Aq. destil., f℥xvj.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA ACADEMY OF SURGERY.

MEETING OF JUNE 7, 1880.

The President, DR. S. D. GROSS, in the Chair.

COMPLETE OUTWARD LUXATION OF THE BONES OF THE FOREARM AT THE ELBOW.

DR. J. EWING MEARS reported a case recently under his care at St. Mary's Hospital. The man was working near some machinery, when a revolving timber struck him on the inside of the right arm, just below the elbow. A complete dislocation of the bones of the forearm occurred. The upper ends of the radius and ulna lay above the outer condyle of the humerus; the arm was flexed at a right angle, and the palm of the hand turned towards the left side, with the fingers partly flexed. There was pain in the fingers and numbness in the distribution of the median nerve. The lower end of the humerus was readily felt beneath the tissues, which were firmly stretched over it, and there was apparently laceration of the tendon of origin of the muscles, arising from the inner condyle. No fracture was discovered, and but little motion was possible.

Reduction was effected by extension, counter-extension, and manipulation, and an angular splint was employed for five days. Subsequently passive motion was instituted and the angle of the splint varied. The patient has now good use of the limb, with but little stiffness.

Complete outward dislocation of the elbow is of rare occurrence. The mechanism of the injury in this case is easily understood, and was evidently due to rotatory and opposing force. The man, at the time of injury, was holding and drawing downwards upon a beam over his head, and had the elbow flexed.

Dr. S. W. Gross stated that he had reduced a backward dislocation of the head of the radius of nine weeks' duration. The patient, who was a farmer 28 years of age, and had fallen from a wagon, came to his clinic with the arm semiflexed, fixed, and pronated, and the head of the bone could be distinctly felt in its new position on the posterior surface of the external condyle of the humerus. Under ether, ordinary manipulations having failed, after the periarticular adhesions had been broken up by forced flexion and extension the dislocation was reduced in a few minutes with the aid of the pulleys.

Dr. O. H. Allis was unable to reduce the dislocation in an instance of this kind, which came under his notice eight weeks after the receipt of injury. The man has permanent deformity of the elbow, and the outer condyle is masked by the displaced bones of the forearm.

Dr. S. W. Gross had reduced a posterior luxation five weeks after the injury.

Dr. Mears was of the opinion that the difficulty in reducing old luxations of the elbow was dependent upon the important part played by the muscles in relation with the joint after plastic exudation had occurred. The ligamentous structures about the joint are rather simple, and yet neglected dislocations in this region are seldom reduced.

Dr. De F. Willard read a paper on a "Splint for Hip-Injuries, including Hip-Joint Disease and Fracture of the Femoral Neck" (see p. 71).

Dr. J. H. Packard spoke of a splint, which had a sort of saddle under the tuberosity of the ischium, that he had employed in coxalgia, and which he had described at a meeting of the College of Physicians about fifteen years ago.

RADICAL TREATMENT OF HYDROCELE BY INJECTION OF CARBOLIC ACID.

Dr. R. J. Levis stated that in 1872 he had begun to treat hydrocele with carbolic acid injections, because a more plastic grade of inflammation than that obtained by ordinary injections was required, and because incision gave rise to cure only through suppuration. His method is to withdraw the fluid by an ordinary trocar, and then to introduce the long nozzle of a syringe through the trocar into the vaginal sac. By this means the carbolic acid is thrown into the cavity, and there is no danger of its being injected into the cellular tissue of the scrotum. The carbolic acid crystals are merely liquefied by slight heat, or by a few drops of glycerin. To keep the injecting fluid ready for use at all states of temperature, about ten per cent. of glycerin or water may be added to the crystals. In summer the crystals become liquid without the addition of any solvent. The amount of carbolic acid which Dr. Levis injects is one-half a fluidrachm, and this is allowed to remain in the vaginal tunic. The operation is almost, if not entirely, painless, because of the local anæsthetic action of carbolic acid. The patients sometimes exclaim at the moment of introduction, but have a sensation of numbness rather than of pain. The pain, when tincture of iodine is employed, is much greater. Care should be observed to allow no acid to flow upon the external surface of the scrotum, for pain and inflammation will follow such contact. After the injection the patient is permitted to walk about the house until the weight and slight soreness of the scrotum cause him to lie upon a bed or lounge. The results after this method of treatment are excellent, for undue inflammation does not occur, there is no marked pain, and a radical cure generally occurs. Dr. Levis has never seen suppuration or sloughing follow this manner of dealing with hydrocele.

Dr. J. H. Brinton had seen quite severe inflammation follow the carbolic acid injection, and Dr. S. W. Gross had failed to cure a case in which he had employed it.

The President introduced Dr. F. H. Anders, of the Sandwich Islands, who gave the Academy an account of the leprosy as occurring in that country.

JOHN B. ROBERTS,
Recorder.

REVIEWS AND BOOK NOTICES.

THE MANAGEMENT OF CHILDREN IN SICKNESS AND IN HEALTH. A Book for Mothers. By AMIE M. HALE, M.D. Philadelphia, Presley Blakiston, 1880.

This little book hits the desired medium between too much and too little advice. It is very clearly and pleasantly written, and from its pages one could easily cull a hundred maxims, besides the "aphorisms" which the author has appended. The mother, guided by this book and by a fair amount of common sense, will less often send for the physician unnecessarily, and also less often omit to send when there is real need. While here and there a fault-finder might object to little things, it would be hard to find or to write a better book of the kind. E. W. W.

TRACHEOTOMY IN LARYNGEAL DIPHTHERIA (MEMBRANOUS CROUP), WITH ESPECIAL REFERENCE TO AFTER-TREATMENT; to which are added a few General Remarks on Diphtheria and its Earlier Treatment. By ROBERT WILLIAM PARKER, Assistant-Surgeon to the East London Hospial for Children, late Resident Medical Officer, Hospital for Sick Children, Great Ormond Street. London, David Bogue, 1880. 8vo, pp. 82. Illustrated.

This commendable essay, republished, with additions, from the most recent volume of the "Transactions of the Royal Medical and Chirurgical Society of London," is worthy the permanent form in which it is now presented. It is chiefly a personal expression of opinion, based upon quite a limited number (twenty-one) of cases of tracheotomy detailed in the volume, sixteen of which operations were performed by the author. Twelve recoveries followed these twenty-one operations,—a highly-flattering result, as far as it goes. Much stress is justly laid on the details of the treatment after operation,—a subject so thoroughly discussed by Sanné that we cannot avoid surprise at missing all allusion to that observer in the text.

Mr. Parker believes in the identity of croup with diphtheria. He recommends a special shape of canula in preference to those in general use; he seems to have more confidence in local applications to the diseased surfaces than have most practitioners, and is

a great advocate for the use of steam by the croup-kettle after the operation. He appears to be unaware of the use of the fumes of slacking lime.

While we believe that greater experience will lead Mr. Parker to modify many of his opinions and methods of expressing them, we commend his monograph to the attention of those likely to be called upon to perform the operation in question, as the details of the after-treatment—a most important element of success—are clearly discussed and appropriately illustrated. J. S. C.

HYGIENE AND EDUCATION OF INFANTS; OR, HOW TO TAKE CARE OF BABIES. By the SOCIÉTÉ FRANÇAISE DE HYGIÈNE, Paris. Cincinnati, Robert Clark & Co., 1880.

Ten prize memoirs termed "remarkable," and containing "valuable material," have been skimmed of their cream, which forms the contents of the "Hygiene and Education of Infants." Though somewhat peculiar in phraseology, and reading a little as did the "Manual for Mothers" of the olden time, a careful inspection will discover very few errors. What few corrections were imperative for the differences of our climate and customs the translator has briefly indicated in foot-notes.

The statistics of infant mortality in France for bottle-fed infants (p. 12) looked so bad that the translator, in a spasm of patriotism, has added a foot-note to say that "Fortunately these facts are not applicable to any portion of the United States." The truth is, however, that they are exceedingly applicable, hand-feeding in our large cities and in many smaller manufacturing towns exhibiting the same unfortunate mortality. The translator was obliged to render into English the honest words of one who, forgetting his national vanity, said, "To tolerate bottle-feeding at Paris is to absolve infanticide."

We come across many excellent hints in reading, as on page 29: "When on several successive days the baby takes each time all the contents of the bottle to the last drop, increase the proportion of milk and diminish the water;" and (p. 49), "An infant should not be weaned while it has an odd number of teeth." Beds of sea-moss, fern-leaves, or fine heather, easily renewed, are advised, and light should not be excluded from the room, either in sleeping or waking hours, from the infant's earliest days.

In short, it is a cheap, safe, and reliable little book to place in the hands of a mother, —one that neither aims at making her a family physician nor confuses her with technical language. E. W. W.

CONDITION OF THE PARIS SEWERS.—Some five men who went into a Paris sewer for the purpose of cleaning it were killed instantaneously by noxious gases.

GLEANINGS FROM EXCHANGES.

OPHTHALMIA NEONATORUM — PURULENT CONJUNCTIVITIS.—Dr. J. R. Wolfe, in a lecture on this subject (*Med. Times and Gaz.*, vol. ii., 1880, p. 259), says he has found that the larger number of the incurable blind owe their misfortune to the purulent ophthalmia of infancy. He urges upon practitioners the importance of abandoning the old routine treatment for this difficulty, and suggests the following measures. The diagnosis of the affection is as follows. On the third or fourth day after birth the baby's eyelashes are found stuck together with crusts forming at the borders, which are red. Next day the lids are more swollen, and the conjunctival sac filled with transparent, yellowish-colored serum and mucus. Within a week all the symptoms become intensified, and there is a copious discharge of pus, which runs over the cheeks. The eyelids are swollen so that they can only with difficulty be opened, and the cornea is found hidden and retracted in the purulent discharge. The cause of the trouble is that the child, in its passage from the uterus, has had its eyes inoculated with gonorrhœal or, possibly, leucorrhœal discharge from its mother's genital organs. The suppuration goes on in the eye until the reproduction of epithelium cannot keep pace any longer with the pus-formation; then the covering becomes imperfect; the conjunctiva and subconjunctival tissues are attacked at the limbus; ulceration or abscess of the cornea ensues, ending in perforation; the eyeball bursts; the lens is evacuated; and the ball shrinks. Should the eye escape disorganization in some of the milder attacks, opacity of the cornea is left behind, causing strabismus, amblyopia, nystagmus, or opacity of the lens-capsule (capsular cataract).

If the old-fashioned, deleterious treatment is followed, which consists in dropping a solution of argenti nitrat. (gr. x ad ℥j) into the eye, the effect is either that the pus washes away the solution, rendering it innocuous (for it never touches the diseased surface), or it irritates the cornea, denuding it of its protective epithelium; the cornea ulcerates, or an abscess is formed, leading to the disorganization just referred to. Meanwhile, the eyelids swell so that the ball cannot be examined, and when the swelling goes down the eye is found to be gone.

Dr. Wolfe's procedure is as follows:

1. When seen in the first stage, before the purulent discharge has set in, the patient's head is placed on a towel and secured on the doctor's knees. The lids are then everted, singly or together, and, after cleaning them with dry lint, he touches the conjunctival surface with lint dipped in this solution:

℞ Boracis, gr. x;
Aq. rosæ, f℥j;
Aquæ ad f℥vj.—M.

One dessertspoonful in two ounces of warm water.

He then puts a few drops of the solution of atropin upon the conjunctival surface:

℞ Atropiæ sulph., gr. j;
Aquæ, f℥ij;
Glycerinæ, f℥ss.—M.

The application is repeated three times a day. The atropin has an antiphlogistic effect upon the inflamed surface, and also, by dilating the pupil, relieves the tension of the eyeball. Dr. Wolfe never uses cold applications, nor does he employ ointments to keep the lashes from sticking together; washing with warm water is better. Dry lint is then applied to the lids and secured by an immovable bandage. The case is watched carefully.

2. When the case is found to be unmistakably one of purulent ophthalmia, the lids are everted one after another, dried as before; a few drops of the solution of atropin dropped in, the surfaces touched with a stick of argenti nit. two parts, potass. nit. one part, and a few more drops of atropin put upon the cauterized surface. When the conjunctival surface is bleeding (a favorable symptom), it is dried with lint and the cauterization repeated. The whole conjunctiva is touched, and also the *cul-de-sac*. He bathes it with lint and warm water, and covers the eyes with dry lint and a bandage. If one eye only is affected, the other is closed with court-plaster and covered with lint.

3. When called to see a case in the stage of advanced suppuration, say of three or four weeks' standing, the eyelids must be opened with great care, as the eyeball may be ruptured. If the cornea is found intact, the atropin and nitrate of silver pencil are to be used.

4. When an ulcer of the cornea or an abscess has already formed, it is the more urgent to use the nitrate as the only weapon to combat the disease. When the cornea is not actually ruptured, Dr. Wolfe generally manages to arrest the progress of the disease, and save it even if it is found in the process of softening or with an abscess. Such cases should be seen daily. In public hospitals or dispensaries Sundays must not be excepted, for one day's neglect may prove disastrous.

Ligation of the Subclavian Artery—Recovery.—Dr. John A. McKinnon (*Virginia Medical Monthly*, October, 1880, p. 524) operated in a case of traumatic aneurism following a gunshot wound, ligating the subclavian artery external to the scalenus anticus. The patient did well until the tenth day, when a profuse secondary hemorrhage took place. Anticipating this, Dr. McKinnon had prepared a bag of shot to be used as a compress should this accident occur.

The bag was made after the form and shape of a United States mail-bag, making the bottom very much larger in proportion to its length; the bag was large enough to hold the shot loosely. He used quilt-lining in its construction, for reasons afterwards to be explained. In the bag he put two and a half pounds of shot.

As soon as possible after reaching his patient, who was nearly dead from loss of blood, the wound was opened, clots removed; a free arterial flow was seen: a strip of adhesive plaster was so applied as to approximate the edges of the wound; and the bag of shot, dipped in the carbolized water, was placed over the incised and pistol-shot wound,—the aneurism pulsation being feebly felt. The hemorrhage was at once arrested. After twenty-four hours the patient complained so much of the weight that Dr. McKinnon emptied out about one-half of the shot from the bag and then replaced it. This remained on for forty-eight hours, when it was permanently removed.

The wound at once took on healthy action; the suppuration was very much diminished in quantity, and nothing more was done, except that the absorbent cotton was kept wet with carbolized oil, consisting of two drachms of carbolic acid to six ounces of the best olive oil.

The only subsequent trouble was the removal of the ligature, which remained until May 14.

Dr. McKinnon devised an elastic bandage, attached to the fore end of the ligature, which was, after as much tension as could be borne, secured with adhesive plaster over the shoulder. This, after about a week, caused the ligature to cut through the artery and become detached. Nourishment and opiates were assiduously attended to. By the end of two months the patient's convalescence was complete, except a partial paralysis of the arm, which was gradually improving.

Fracture of the Axis.—"A Medical Student" (*North Carolina Med. Jour.*, September, 1880, p. 159) gives an account of this fracture in a person executed by hanging. He had a fall of nearly eight feet, and was pronounced dead by the attending physicians about fifteen minutes after the trap was sprung. In the death-struggle nothing unusual was noticed. There were a few convulsive strokes of the limbs and the customary drawing up of the legs; soon after, his heart stopped pulsating, and death had cast her dark veil over his earthly existence. On examining the rope, it was found that the knot had slipped from under the ear and was resting above the atlas, necessarily throwing the head forward and the weight of the body on the axis. In hanging, the rope is supposed to be properly adjusted with the knot under the ear, but it often slips to the back or front of the neck, and the condemned man, ten chances to one, dies from asphyxia.

An oblique line of ecchymosis around the neck was distinctly seen, much darker than

the surrounding skin. The muscles of the neck were carefully dissected away and the atlas and axis exposed, showing the axis in close contact with the spinal cord. On examining the dura mater, pia mater, and arachnoid membranes of the cord, the two latter appeared much congested, some of their vessels having given way, thus allowing an effusion of blood into their cavity. The pressure of the fractured bone had partly broken down the anterior columns of the cord at the point of contact. The detached axis exhibited fracture on both sides at the junction of the body with the pedicles running across the transverse processes, parallel with the posterior portion of the body. The ligaments of the odontoid attachment and the odontoid process were uninjured. Fracture of the odontoid process in hanging is by no means common, but one at the above-named place is yet more rare.

The writer also mentions the case of a milkman who, while riding under a gateway, accidentally struck his head on the cross-bar over a gate. He apparently experienced no pain, but drove on until a movement of his head brought the odontoid process to bear on the spinal cord, which caused him to fall lifeless.

Results of Galvano-Puncture in Aneurism of the Aorta.—At the meeting of the French Medical Association at Rheims (*Med. Times and Gaz.*, vol. ii., 1880, p. 275; from *Union Méd.*, August 21) Dr. Petit stated that he had collected 114 cases, in 69 of which amelioration had taken place; in 38 death had taken place without any notable amelioration; in 3 no result is given; in 4 this was doubtful. In 39 cases the patients survived less than a year, although greatly ameliorated; and 10 survived from one to two years, the remainder surviving from two to five years. Amelioration was produced in 24 cases after a single application, and continued from two to seventeen months. In the others from three to eleven or twelve applications have been required, owing to the short duration of the amelioration, these patients succumbing shortly after the last application. In intra-thoracic aneurisms there were 30 successes to 7 failures, while among aneurisms which manifested themselves externally there were 36 successes to 31 failures. Amelioration was especially manifested with respect to the symptom of pain; and cessation of paroxysms of dyspnœa, return of appetite, sleep, etc., have also been observed. In 61 cases aggravation of symptoms is recorded; and this has been especially the case when the negative pole has been employed.

Professor Potain observed that it was an error to attribute to the production of coagulation the amelioration induced by electrolysis, and that it is a good thing that this is so, as embolism would be of frequent occurrence. Dr. Onimus also attaches little importance to coagulation, believing that the current exerts a vital and molecular action, to which the amelioration is due. When a coagulum is found in the aneurism, it is a mistake to attribute it to the electrolysis, as it is also met with when this means is not employed. M. Ollier observed that no case of durable cure has been recorded, and he prefers treatment by milk-diet and the iodide of potassium. Dr. Heurot considered it as a valuable palliative, relieving distressing symptoms even in desperate cases. M. Petit replied that, while a cure has been obtained only in two or three cases, very prolonged amelioration has followed in a great number.

Fœtal Endocarditis.—In the case of a pregnant girl of seventeen, under the care of Prof. Peter (*La France Méd.; Lancet*, vol. ii., 1880, p. 388), an active fœtus could be felt in the uterus; but instead of the usual *tic-tac* sound of the fœtal heart the first sound was replaced by a blowing murmur, almost immediately succeeded by a sharp sound like the normal second sound, and this was followed by a brief silence. The precise limitation of this sound to the area in which alone the sounds of the fœtal heart were heard, and the absence of any uterine contraction which could cause compression of the umbilical cord, showed that the sound must be due to a lesion of one of the cardiac orifices.

On examination of the child, which died during the last period of labor, the organs were found healthy, except the heart, which was enormously hypertrophied and seemed alone to fill the thoracic cavity. It was nearly globular in form, the right half being much larger than the left. The valves on the left side of the heart and those of the pulmonary artery were healthy, but the tricuspid valve was the seat of a "plastic vegetative endocarditis," the free edge being thickened, covered with projections, and its upper surface being uneven. The chordæ tendinæ were shortened and thickened, maintaining the valves in contiguity to the walls of the ventricle, so that it was impossible for them to fulfil their normal function. The right ventricle was dilated and greatly hypertrophied. The lesson to be drawn from the case is that when fœtal endocarditis has been diagnosed acceleration of the labor by all possible means is desirable to afford the child a better chance of life. The mother, it may be noted, had never suffered from rheumatism, and presented in her history nothing to which the condition of the fœtus could be ascribed. Whether she had suffered from syphilis was not noted.

Easy Expulsion of Biliary Calculi.—Dr. R. Kennedy (*Lancet*, vol. ii., 1880, p. 456) recommends the use of olive oil in large doses for the purpose of expelling biliary calculi. He has used it in a variety of cases in the past year, and always with complete success. In every instance in which the calculi were proved or presumed to have been the cause

of periodic suffering, these bodies were promptly and painlessly expelled in larger or smaller numbers by the use of *large* doses of olive oil. In some instances, where the patients did not exhibit symptoms of such acute suffering as are more commonly witnessed, but where obstruction to proper flow of bile was evident, satisfactory results have been obtained. In one case, given by Dr. Kennedy, six ounces of oil were taken at bedtime, followed the next morning by a full dose of castor oil. The bowels were not moved until the following evening, when an enema was given, which brought away a large number of small stones. The dose was repeated on the two following nights, and no more trouble ensued from the calculi. The administration of olive oil at intervals of a few weeks or months does prevent the reformation of the concretions, but does not do away with the causes or the diathesis upon which their formation depends.

CAUSE AND TREATMENT OF BROMIDROSIS OF THE FEET.—Dr. Thin, in a paper on the cause of the bad odor sometimes associated with excessive sweating of the feet (*Brit. Med. Jour.*, vol. ii., 1880, p. 463), calls attention to the fact that this odor does not belong to the sweat itself, but is in the coverings of the feet. In a case experimented upon to verify this fact, which has been noted by Hebra, the hands of the patient, a young woman, which sweat profusely, were free from odor, while the feet gave out a disagreeable smell in moist weather, being quite inoffensive in dry, bracing weather. The soles of the shoes and stockings being subjected to the action of an antiseptic, the smell was entirely banished. It soon returned, however, and examination showed the stockings to be saturated with a secretion filled with bacteria. When, however, the stockings were immersed in a jar containing a saturated solution of boracic acid and dried, the smell disappeared. Taking this hint, these coverings were disinfected with the acid previously to wearing, with good result. To prevent the sodden, disagreeable smell of the shoe-soles due to this same cause, the patient was directed to get cork soles. Each pair of these, after having been worn a single day, were placed overnight in the boracic acid solution, and were the next day dried. On the third day they were again ready for use. The skin was also washed with the boracic acid solution, which hardened and refreshed it. The cure was very satisfactory.

OIL OF EUCALYPTUS.—Dr. Siegen (*Lancet*, vol. ii., 1880, p. 387; from *Deutsche Med. Wochens.*) has been using the oil of eucalyptus in antiseptic surgery. He prepares a solution of the oil by dissolving three grammes in fifteen grammes of alcohol, and diluting with one hundred and fifty grammes of water. In this solution he soaks ordinary gauze. This dressing is applied in the wet state, covered with the usual gutta-percha tissue, and the whole kept in position by means of gauze bandages. Thus prepared, the eucalyptus gauze does not appear to irritate or produce eczema upon even sensitive skin, and is perfectly antiseptic.

In one case of a child with caseous glands of the neck, the instruments were dipped in a two-per-cent. solution of the oil, the surfaces were washed with the same, and the operation performed by scooping out the contents, draining, and applying a wet eucalyptus dressing as above described. Although the spray was not used in this case, the discharges which had penetrated the gauze were quite sweet upon the third day. The slight amount of pus remained odorless, and on the eighth day the cavities had contracted and healed. Cases of resection of joints, etc., are also reported by Dr. Siegen, where the eucalyptus oil worked very well.

TINNITUS AURIUM.—In a paper on the forms, causes, and treatment of tinnitus aurium, Dr. W. Douglas Hemming gives the following table, showing the classification of noises in the ear, together with the causes producing them:

KIND OF NOISE.	CAUSES.
1. Tidal "to and fro" noises, like the sound produced when a shell is held to the ear.	Tobacco; chronic catarrh of the middle ear, ending in undue contraction of intrinsic muscles.
2. Humming or buzzing noises, like the sound of a humming-top or the buzzing of a bee.	Impacted cerumen, eczema, foreign bodies or parasites in the external meatus.
3. Gurgling or bubbling noises, as of air bubbling through fluid.	Fluid in either (*a*) the tympanum or (*b*) the Eustachian tube; the result of catarrh.
4. Rustling or crackling noises.	Deficiency of cerumen (hairs in the meatus or on the membrane give sounds like an æolian harp); acute catarrh in its later stages
5. Constant rushing noises, like the falling of water in a cataract.	Venous congestion of the labyrinth.
6. Pulsating noises, often said to be like the beating of a drum; frequently synchronous with the pulse.	(*a*) Extra-aural causes, anæmia, aneurism, etc.; (*b*) arterial congestion of the labyrinth.

EXTRA-UTERINE PREGNANCY SUCCESSFULLY RELIEVED BY ABDOMINAL SECTION.—Mr. Lawson Tait gives notes (*Lancet*, vol. ii., 1880, p. 456) of the fifth case of abdominal section for extra-uterine pregnancy coming under his care. On opening the abdomen, the pregnancy was found to be seated in the right broad ligament, the Fallopian tube having ruptured at its lower aspect and the ovum escaped into the tissues between the folds, as had been the case in all the instances he had operated upon. He made an opening at the upper and anterior part of the cyst, removed the child, which it was previously ascertained was quite dead, cleaned out the cavity, stitched the margin of the wound in the cyst to the wound in the abdominal wall, and left in a wide glass drainage-tube. All the details have been previously described at length in Mr. Lawson Tait's record of his previous case, published by the Royal Medico-Chirurgical Society. During the following

three weeks the placenta came away in pieces, the cavity gradually closed, and the patient left the hospital in perfect health.

PURULENT CONJUNCTIVITIS CAUSED BY INOCULATION FROM ULCERS OR OTHER DISCHARGES.—Dr. J. R. Wolfe (*Med. Times and Gaz.*, vol. ii., 1880, p. 260) says there can be no doubt that purulent conjunctivitis may be produced by inoculation from other than gonorrhœal or leucorrhœal discharges. A little girl three years of age had been troubled for four or five days with a serious inflammation of the right eye. On examination, the conjunctival sac was found filled with a yellowish, ichorous discharge, not like the creamy discharge in infantile ophthalmia. Dr. Wolfe had no doubt that it was a case of inoculation. On inquiry, he found that the nurse was suffering from ozæna, and bloody pus from her throat or nostrils was found upon the pillow. The smell was so offensive that every morning the window had to be opened before the child's mother could enter the nursery. As the child was the nurse's bed-companion, there could be no doubt how the disease originated. The case did well, without leaving any trace behind after ten days' treatment.

TREATMENT OF SEA-SICKNESS.—Dr. Beard recommends the bromides, particularly the bromide of sodium, taken in large doses for one to three days before sailing, so as to produce a mild bromism, and this bromism should be kept up during the voyage if necessary. In addition, sulphate of atropia in doses of $\frac{1}{100}$ to $\frac{1}{25}$ grain may be given hypodermically or by the mouth, and repeated with sufficient frequency to produce great dryness of the mouth. This treatment may be adopted alone or with the bromides. Atropia will sometimes be enough alone, and it prepares the way for the bromides. Powdered citrate of caffein in two- or three-grain doses is useful in the sick-headache; or, as this causes wakefulness if given in the latter part of the day, cannabis indica in pills of $\frac{1}{2}$ to $\frac{1}{3}$ grain may be substituted.

UTERINE FIBROIDS CURED BY PREGNANCY.—Dr. A. N. Talley reports (*Virginia Med. Monthly*, October, 1880, p. 552) the case of a colored woman of 36 who had never borne any children, and who consulted him for an abdominal tumor. On examination, a multiple tumor consisting of four or five irregularly spheroid growths from small walnut to orange size embedded in one common tissue was discovered. The diagnosis of multiple extra-uterine fibro-cystic tumor was made. The growth increased in size for several months, when the woman became pregnant. On examination after labor, which was normal, no trace of the tumor was found, and some months later it showed no sign of returning.

VOMITING AS A SYMPTOM.—Prof. Potain, in a lecture on this subject (*Med. Times and Gaz.*, vol. ii., 1880, p. 401; from *Revue Méd.*), says there is in general much more vomiting in an affection of the brain or in disease of the kidney than in affections of the stomach, except cancer which has reached a certain stage. So that when one is in the presence of a patient who is constantly vomiting alimentary matters without the digestive organs manifesting any well-marked sign of disease, attention should always be immediately turned to the encephalon and to the organs for the secretion of urine.

FLACCIDITY OF THE IRIS AS A SIGN OF REAL DEATH.—Dr. Boyd B. Joll writes to the *British Medical Journal* of September 25, referring to a condition of complete flaccidity of the iris as a sign of real death. He says that it can easily be shown by synchronous compression of the globe of the eye in two opposite directions, when the pupil will readily assume an oval or irregular shape, whereas in apparent death no ordinary amount of compression in this manner will have the least effect in altering the circular form of the pupil. [A communication in a later number of the *Journal* goes to show that this sign cannot invariably be depended upon.—ED.]

TEST FOR ARSENIC IN WALL-PAPERS, ETC.—Dr. Henry Barnes gives the following easy test to detect arsenic in paper-hangings, etc. Immerse the suspected paper in strong ammonia, on a white plate or saucer: if the ammonia becomes blue, the presence of a salt of copper is proved; then drop a crystal of nitrate of silver into the blue liquid, and if any arsenic be present the crystal will become coated with yellow arseniate of silver, which will disappear on stirring.

GUNSHOT WOUND OF THE MEDIAN NERVE.—Mr. Lawrie communicates to the *Lancet* (vol. ii., 1880, p. 575) the case of a boy of 10, who was accidentally struck in the right arm by a charge of small shot. Several pellets were removed from underneath the skin in the neighborhood of the elbow, but none appeared to have penetrated more deeply. A good deal of superficial inflammation followed, and the boy lost the use of his forearm and hand. It was not clear whether this paralysis was immediate or came on gradually. Great and increasing pain in the arm and corresponding side of neck and body. Examined three months after the accident, a very peculiar drop of the right wrist was observed, with loss of power in the forearm and exalted sensibility in the palm of the hand. There was much glandular and lymphatic enlargement, which obscured the diagnosis, but thickening of the median nerve was satisfactorily made out about the middle of the arm, and Mr. Lawrie therefore cut down upon it, with antiseptic precautions. When exposed, the nerve was more than twice its proper size, and he was about to stretch it, when he detected a hard body in its interior. Instead of stretching, a longitudinal incision was made into its substance, and a pellet found and removed. The wound healed by

first intention, and the boy rapidly recovered power in the forearm and normal sensation in the hand, and was discharged cured in ten days.

New Method of Treatment in Prolapsus Ani.—Professor Kehrer (*New York Medical Record;* from *Deut. Med. Wochens.*, August 14) folds together a portion of the sphincter, and, after excision of its mucous covering, secures the folds by means of a firm suture. Thus a portion of the ring is eliminated, and the calibre narrowed correspondingly. In two cases subjected to this operation a speedy cure took place.

MISCELLANY.

Chronic Accidental Poisoning from Arsenical Wall-Papers.—In a paper on chronic accidental poisoning (*Practitioner*, vol. xxv., 1880, p. 175) Dr. Henry Barnes calls for legislative interference for the prevention of chronic poisoning from arsenic as contained in wall-papers, toys, confectionery, artificial flowers, etc. A paper on this subject, presented before the Medical Society of London, showed that out of one hundred cases thirty-two had occurred in the families of medical men, showing the difficulties attending the diagnosis of this form of poisoning. Dr. Barnes adds to the evidence already accumulated two cases coming under his personal observation. He draws the following conclusions:

1. Arsenical wall-papers are in common use. 2. These papers are capable of producing serious and even alarming symptoms in some persons inhabiting the rooms in which such papers are hung. 3. Legislative interference is desirable in the direction of imposing some check upon the free and unrestricted sale of poisoned articles. 4. Until such legislation is obtained, medical men should urge their patients to purchase only such wall-papers as are guaranteed "free from arsenic."

Treatment of Sprains.—Dr. R. Dacre Fox (*Brit. Med. Jour.*, vol. ii., 1880, p. 504) suggests the following treatment. It may be divided into two stages; the first lasting from a day to a week or longer, during which the treatment has to be directed to averting inflammation by rest, warm applications, anodyne lotions, etc.; the second commencing when the joint has become cold, swollen, and painful on movement,—in fact, when the injury has assumed a more or less chronic character. This consists of pressure applied (around the ankle, for instance) as follows. The normal hollows about the joint are developed as far as possible by kneading the swollen and œdematous tissues which have obliterated them; then five pads of tow, lint, or leather, about one inch by two to four, adapted in shape to the normal hollows, are applied. They may, in old chronic cases, be fastened in place by a long, extended, half-moon-shaped piece of plaster (emplastrum saponis spread on leather), long enough for the ends to overlap in front when the heel is placed in the centre, and a narrow, oblong piece above this, placed around the lower part of the leg, to cover the upper part of the pads. The handiest way to apply the pads is to apply an elastic ring over them, which may be cut when the oblong piece of plaster is put on. Lastly, the whole ankle is to be firmly bandaged.

The Vienna Medical School has sustained severe losses of late,—Rokitansky, Schuk, Oppolzer, Hebra, Skoda, Sigmund, and Hyrtl, constituting a constellation of teaching-power that, perhaps, has never before been assembled together in one school; and now all, as teachers, have disappeared, for, although the three last named are still living, they have retired from the faculty.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM OCTOBER 17 TO OCTOBER 30, 1880.

Baily, E. I., Lieutenant-Colonel and Surgeon.—When relieved by Surgeon Moore, to proceed to Wilmington, Del., and report by letter his arrival to the Surgeon-General.—S. O. 232, A. G. O., October 28, 1880.

Moore, John, Major and Surgeon.—Relieved from duty with Army Medical Examining Board in New York City, and to report in person to Commanding General, Department of the Columbia, for duty as Medical Director of that Department. S. O. 232, A. G. O., October 28, 1880.

Spencer, W. C., Major and Surgeon.—Assigned to duty at Fort Snelling, Minn. S. O. 129, Department of Dakota, October 25, 1880.

White, C. B., Major and Surgeon.—To report in person, at the expiration of his present leave of absence, to the Adjutant-General of the Army, for special duty in connection with the Recruiting Service. S. O. 229, A. G. O., October 25, 1880.

Caldwell, D. G., Captain and Assistant-Surgeon.—Assigned to duty as Post-Surgeon at Fort Fred. Steele, Wyo. T. S. O. 98, Department of the Platte, October 20, 1880.

Matthews, W. C., Captain and Assistant-Surgeon.—His assignment to duty at Cantonment on the Uncompahgre River, Col., revoked, and he is assigned to duty at Fort Wingate, New Mexico. S. O. 229, Department of the Missouri, October 16, 1880.

Torney, G. H., Captain and Assistant-Surgeon.—When relieved by Assistant-Surgeon Matthews, to proceed to Fort Lyon, Col., and report to the Post-Commander for duty. S. O. 229, c. s., Department of Missouri.

Wood, M. W., Captain and Assistant-Surgeon.—At the expiration of his present leave of absence, to report in person to Commanding General, Department of the East, for assignment to temporary duty. S. O. 232, c. s., A. G. O.

Cuningham, T. A., First-Lieutenant and Assistant-Surgeon.—Granted leave of absence for six months, with permission to go beyond sea. S. O. 227, A. G. O., October 22, 1880.

Burton, H. G., First-Lieutenant and Assistant-Surgeon.—Granted leave of absence for two months, with permission to apply for one month's extension. S. O. 230, A. G. O., October 26, 1880.

Gibson, R. J., First-Lieutenant and Assistant-Surgeon.—Relieved from temporary duty at Fort Leavenworth, and assigned to duty at the Cantonment on the Uncompahgre River, Col. S. O. 229, c. s., Department of the Missouri.

PHILADELPHIA, NOVEMBER 20, 1880.

ORIGINAL LECTURES.

CLINICAL LECTURE.

A SKETCH OF A CASE OF PROBABLE REMITTENT FEVER WITH CEREBRAL SYMPTOMS, WITH POST-MORTEM EXAMINATION.

Delivered at the Philadelphia Hospital

BY EDWARD T. BRUEN, M.D.,

One of the Physicians to the Hospital, and Demonstrator of Clinical Medicine in the University of Pennsylvania, etc.

GENTLEMEN,—Last year, about this time, I presented for your study some cases of anasarca which developed as the sequence of deficient vaso-motor tonus. I endeavored to prove that the action of the malarial toxæmia was sufficient to suspend the action of the nervous system governing arterial tension, and to bring about increased exudation from the blood-vessels, and diminished absorption. I also showed you that the secretion of sweat was not alone dependent on the blood-supply of the cutaneous vessels, but is also under the control of the innervation of nerves supplying the cutaneous glands, and that a suppression of the functional activity of the skin was also a possible factor in malarial anasarca or effusion into pleural sacs. These cases and my arguments in support of my position can be found in the *Philadelphia Medical Times* for December 21, 1879, in the Proceedings of the County Medical Society. To-day I wish you to note a case in which the malarial poison has expended its force upon the cerebral nervous system.

Morris F., æt. 36, has been for two years a servant in the house of the superintendent of this hospital, and enjoyed excellent health. During the first two weeks of October of this year he complained of malaria, but did not give up his occupation. On the 17th he was found in his bed, in the morning, delirious, and the temperature, as taken by his physician, was 103° F.; in the evening it was 101°. The 18th, A.M., temperature was 105°; in the evening 101°. The 19th it was 104° in the morning; in the evening $104\frac{3}{5}$°. I saw him at noon of the 19th. His mental state resembled that of acute mania. He was singing, talking rapidly, shouting, and the attendants could scarcely restrain him in bed. The pupils responded to light; no local nerve-paralysis, but there was a clonic spasm of right arm, with a tendency to flex the fingers of the right hand and retain them clenched, and he would *beat* his breast with this arm, while the other limbs were motionless. A spasm of the muscles of the throat rendered swallowing impossible. Wednesday, the 20th, the temperature fell to 98° F., without treatment except a bath of 95° F., given the day before to equalize circulation and favor heat-evolution. In the evening the temperature rose to 102° F. Subsequently the record was as follows: 21st, A.M., $101\frac{2}{5}$; P.M., 102°. 22d, A.M., $102\frac{2}{5}$°; P.M., $104\frac{2}{5}$°. 23d, A.M., 102°; P.M., 103°. 24th, A.M., $101\frac{2}{5}$°; P.M., 102°. 25th, A.M., 100°; P.M., 101°. 26th, A.M., $99\frac{3}{5}$°; P.M., $98\frac{2}{5}$°. Death occurred suddenly on the morning of the 27th.

Many of you saw this case during its progress in the wards. For the benefit of all, let me sketch the salient features of the case. These represent our patient as somewhat rational on the morning of the 20th, sufficiently so to give some account of his personal history, although he was by no means thoroughly rational. The difficulty of deglutition and spasm of the throat-muscle were on this day recognized as hysteroidal in type, for nourishment could be swallowed when food was finally offered to him.

In the evening of that day the delirium returned, and he never afterwards regained consciousness. His mental state became comatose towards the last, although at intervals, when aroused, he would converse incoherently in German, French, or English. Three days before death a paresis of the left buccinator muscle was noted; the cheek on this side seemed to flap loosely inward. He would always show signs of pain if the right arm was lifted or moved, the fingers of the hand were always tightly flexed, the thumb turned inward, though the clonic spasm ceased nearly a week before death. The special senses of sight and hearing were always intact. The urine dribbled involuntarily, and yet the bladder was at times much distended, and the catheter had to be used. There was evidence of some cystitis, with a small amount of albumen and some pus in the urine. The respirations were always about

thirty-two per minute, rather shallow, and for three days before death snoring; the pulse always indicative of arterial fulness, and most of the time the heart acted strongly, though the first few days of the attack the beats were weak. For several days there was bilious diarrhœa, and a large bed-sore formed on the back. There was noticeable increase of splenic dulness.

The diagnosis, the non-effect of treatment, and the post-mortem are points of exceeding interest. The suggestions which entered my mind were, Is this a case of cerebral syphilis? Is it an abrupt development of typhoid fever after two weeks' incubation? Is it a pernicious form of malarial remittent fever? Is it a case of acute specific meningitis, or rapid development of syphilitic disease of blood-vessels or connective tissue in the nervous system? Cases of delirium considered to be of this nature have been reported, and cases not unlike that of our patient.*

The deficiency of pronounced localized symptoms, especially loss of function (paralysis), militated against this view, and yet the clonic spasm of the right arm, the clenched fingers, the pain on moving the right arm, the paresis of the buccinator muscle, had to be accorded their importance. I think no symptom of specific disease of the nervous system is more characteristic than a localized loss or perversion of functional activity, when this is not the direct result of obvious pressure or injury of nerves. Irregular paralysis of limbs on different sides of the body, for example, is characteristic, or even diminished functional activity. The suddenness of the onset favored this view; but when three days had elapsed and still no localized symptoms developed, this suggestion was positively discarded.

The temperature chart afforded the strongest argument against typhoid fever. It was not an ascending scale of higher evening temperature, nor was the elevation a sustained elevation. The most probable hypothesis seemed to be a malarial remittent fever, to which the temperature, the bilious diarrhœa, the slight splenic enlargement, the locality in which the patient lived (notoriously malarial), and the season of the year, seemed to point. Moreover, cases of this kind have come under my notice once or twice. One of the most remarkable was one in which similar symptoms had occurred in a gentleman of gouty diathesis, together with delirium. Much the same series of symptoms were present, only the delirium was less violent. Here, with much persuasion, the regular medical attendant was induced to give forty grains of quinine for two days, and a prompt recovery from all the symptoms ensued. Now note the effect of treatment in our case. As there was scanty evidence of remission, thirty grains of quinine were given in solution on the afternoon of the 20th; the morning of the 21st the temperature was not materially affected; for three days the same amount of quinine was given daily during the apparent remission, with similar results. The drug seemed to reduce the temperature but very slightly, but there was no general improvement in the symptoms. On the 24th and 26th twenty-five grains of quinine were given, and a notable reduction of temperature occurred, but death took place suddenly on the forenoon of the 27th. Small doses of calomel, also cream of tartar, were used occasionally. Counter-irritation to head and neck by means of blisters, and internally bromide of potassium, were all means which were efficiently used. Nourishment was supplied by the rectum and by the mouth, but without avail.

The post-mortem was made six hours after death, by Dr. Formad, microscopist to the hospital, and myself. The brain was examined minutely, and was found to be singularly free from morbid process. There was a slightly œdematous condition of the arachnoid, but not so much as was noted in a case of cancer of the liver, without cerebral symptoms, which was examined at the same time. The liver was natural in size and appearance, macroscopically and microscopically; the spleen was enlarged, weighed sixteen ounces, and was much congested. There was an old cystitis and pyelitis, which accounted satisfactorily for the small amount of albumen and pus in the urine. The cortical and medullary portions of the kidney were healthy, and microscopic study of these organs showed healthy tubules, with slight cloudy swelling of the epithelium. I mention this for your especial attention, as some idea that the symptoms indicated a uræmic condition may have suggested itself to some of you. Note that

* See A Contribution to our Knowledge of Syphilitic Diseases of the Nervous System, by Dr. H. C. Wood, American Journal of the Medical Sciences, October, 1880.

the respirations were thirty-two, the pupils were neither contracted nor dilated, the skin was moist, frequently the urine passed abundantly, and approximate estimation showed the amount of urea normal. These points always excluded uræmia.

To return to the autopsy, a solitary tuberculous ulcer was found in the ileum, probably from absorption of pus from the kidney. Lungs and heart were normal, save that old pleural adhesions were extensive.

Does it not appear that the vital powers had been reduced by the cystitis, and that the system was unable to rally under the malarial toxæmia? It is rare to note so pronounced and persistent brain-symptoms in malarial fever in this latitude: though frequent in Southern climates, here we do not look for them.

I have often seen somewhat similar cerebral symptoms in the course of cases of chronic alcoholism. Frequently have I felt inclined to diagnose meningitis, but have refrained on the grounds already stated. The teachings of this case can, however, be applied to many a clinical picture. I have thought the case might be valuable in teaching caution in making a diagnosis of cerebral irritation or inflammation. I would advise you never to commit yourself to a diagnosis of meningitis without first being satisfied that local symptoms exist; and, in view of the rarity of simple meningitis, remember to inquire for evidence of the prior existence of syphilis.

ORIGINAL COMMUNICATIONS.

HEMORRHAGE INCIDENT TO PARTURITION.

Read before the Philadelphia County Medical Society, October 13, 1880,

BY GEORGE HAMILTON, M.D.

NO untoward event so often attends labor as post-partum hemorrhage, nor does any other condition so frequently occasion anxiety and alarm in the accoucheur. The profuseness and celerity of the discharge will, in many cases, quickly reduce the woman to a condition that affords small hope of escape from the impending danger; and fortunate is he who, in a long practice, has not been compelled to witness his patient sinking quietly away, or frantic from an icy coldness that has seized upon every limb, or writhing in convulsion that has no end but in death. This tragic termination, fortunately, does not often occur; yet it not unfrequently happens that the physician is filled with solicitude as, from time to time, on examining the pulse, scarcely perceptible, beating sometimes very slowly, oftener very rapidly, he observes the blanched face, the pinched features, the increasing coldness of the extremities, with the distressing and irrepressible yawning and jactitation that usually attend such conditions. Yet even under these discouraging circumstances a majority of women, either from great tenacity of the vital principle, or by a prompt and judicious application of remedial measures, will escape a fatal issue.

That a condition so dangerous, or it may be fatal, and in character so well adapted to excite profound sympathy, in the fact that she who has just ushered an infant into life is now threatened with the loss of her own, should have engaged from time immemorial the thoughts and the pens of so many practitioners, is no matter for surprise. Yet, despite all that has been done with a view to the prevention or arrest of post-partum hemorrhage, it still remains the most prominent of the dangers incident to parturition. In this point of view it is most gratifying to observe that, for a short time past, renewed efforts in this direction have been, and are now, in progress for the discovery of some agent or measures more reliable than any heretofore devised to avert the dangers alluded to. In this connection we cannot but commend the action of Prof. Penrose in bringing before the Gynæcological Association, when last in session in this city, the subject of uterine hemorrhage. And, however we may be disposed to hesitate in adopting one or two of the measures proposed for the suppression of hemorrhage without a more extended trial being accorded them, it must still be admitted that the subject, involving as it does the lives of so many individuals, has a supreme importance, exceeding perhaps, with one possible exception, that of all others discussed in that session. In a paper read some time ago before the Philadelphia County Medical Society, by Dr. Charles T. Hunter, upon the use of hot water for the suppression of hemorrhage in surgical practice, allusion was incidentally made by the lecturer to the practice, lately recommended, of injecting the uterus with warm, or even

hot, water in case of post-partum hemorrhage. Bold, or even hazardous, as this procedure might at first view be regarded, cases are cited where the discharge was apparently by this means moderated or promptly arrested. More than forty years ago, through the medium of a nurse, I was told of a country physician who, when the usual treatment failed to arrest the hemorrhage, applied a folded napkin, heated nearly to scorching, over the region of the uterus, with the immediate cessation of the flow as the result, and this he declared was his uniform practice in similar cases. Where heat is applied to the cutaneous surface of such temperature as to cause the sensation of burning, a shivering or decided chill would, especially after cold applications, be likely to occur, just as we observe in cases of severe burning or scalding. The shock to the nervous system in this event is so powerful as nearly always to paralyze, to a considerable degree, the action of the heart and vascular system, as is made manifest by the state of the pulse in all similar conditions, whatever may be the cause. Whether one or the other of these methods of applying heat may be safely and advantageously employed for the suppression of hemorrhage must, of course, be determined by far more numerous trials than have hitherto been made.

The primary object of this paper is not, however, to enter upon the general subject of uterine hemorrhage, but to present for consideration a few thoughts regarding certain embarrassments sometimes encountered in the treatment of post-partum hemorrhage. This, as every practitioner will sooner or later discover, may be moderate and last a considerable time, yet without seriously endangering the life of the woman; whilst, on the other hand, it may be, as before said, fearfully profuse and rapid, destroying the patient in a very short time, or rendering her situation so critical that the accoucheur must remain for hours in anxious suspense, not exempt, perhaps, from sad forebodings that the apartment in which his patient lies is destined soon to become the chamber of death. A case in illustration was Mrs. B——, residing within one square of my present residence, to whom I was urgently called. She was about three weeks short of the full term, and, while seated at the supper-table, without pain or other premonition, she suddenly arose, rushed upstairs, and threw herself upon a bed. On ascending the stairs I noticed a good deal of blood upon them, and a deluge of blood had already escaped from the woman, passed through the bed and bedding, and lay in large amount upon the floor. The face of the woman was blanched, the pulse exceedingly frequent and feeble. On inquiry it appeared that in four or five other confinements nothing untoward had occurred. Slight pains began directly after she reached the bed; the os uteri was found to be already considerably dilated and relaxed. Cold applications, stimulus, and ergot were resorted to. The pains quickly increased, and in a short time the child was born, without apparent characteristic action of the ergot. The flow of blood after pain began, and until the child was born, was very slight, yet in such a case it was of serious importance; and, to add to the difficulty, the placenta was partially adherent, the uterus had not contracted, despite repeated doses of ergot, and occasional slight discharges continued. Believing that, unless the placenta was removed by the hand and the contraction of the uterus thereby effected, the woman must perish, that process was resorted to, and accomplished without difficulty. Yet, notwithstanding the facility of passing the hand into the womb, owing to the unusual relaxation of the parts, increased doubtless by the exhausted condition of the system, she resisted, as nearly always happens in such cases, and the consequence was, not a great, but a decided increase of the flow, though only for a moment or two. From this time the patient began to sink more rapidly; the limbs, especially the feet, legs, and knees, became intensely cold, so that she screamed with agony and violently upbraided two persons engaged actively in rubbing her limbs with heated cloths, and so continued to do until a short time before her departure.

Another case of somewhat similar character came under my care in the country. It was the second accouchement of a pale, anæmic young woman, residing about six miles from my location, and about the same distance from West Chester. The summons came at midnight, and the journey required about an hour. On entering the chamber, a woman in attendance said the child had been born an hour and a half before; that the labor was easy and of short duration, but that in a few moments after the birth

the woman had swooned, and with only partial returns of animation had so continued; and, furthermore, the after-birth had not come away. On examination, an amount of blood was seen to have passed from the uterus which, although not large for a strong woman, was sufficient to account for the prostrate condition of this patient. My presence and questions partly aroused the patient, and in whispers she said that very slight pains were felt from time to time, and a slight discharge followed each pain, but that the greatest loss of blood took place immediately after the birth of the child. The usual measures were at once adopted,—cold applications, stimulants, and ergot. As often happens after the child has passed from the uterus, the ergot failed to act, and, seeing no alternative other than to remove, if possible, the placenta, previously ascertained to be adherent, the hand was with some difficulty introduced, but failed to effect the purpose intended. The muscular resistance of the woman to this manual operation was so strong that, for the moment, an increased discharge occurred. After some delay and giving more stimulus she was induced to submit to another attempt to remove the placenta, but, partly in consequence of the strength of the adhesion, and partly from the embarrassment occasioned by her resistance, the effort again proved abortive. From this time the aspect of the case became more discouraging: her husband was therefore directed to mount a horse and summon, with all haste, Dr. Worthington or Dr. Thomas from West Chester; but before he was prepared to start, so sudden and decided a change took place as to manifest clearly that, if once upon the road, he would never again behold his companion alive. His departure was therefore countermanded, that he might be present to witness the last moments of his expiring wife, whose existence terminated in less than half an hour after he re-entered his humble dwelling.

These cases represent, probably, a majority of those which, under similar circumstances, terminate fatally. In the example first quoted, it was but a very few minutes from the moment the woman left the tea-table until I saw her, yet she was then nearly exhausted. In the second case the principal hemorrhage took place immediately after the birth of the child: so that both women were rendered nearly exsanguineous in a very short time; yet, had there been no further loss of blood, it is almost certain that both would have escaped with their lives. This, however, could scarcely be expected, for under the most favorable aspect of such conditions there will be more or less discharge; and the important question here presents, whether the manipulations resorted to were not contributing agencies to the loss of life. In reference to even slight discharges of blood after profuse hemorrhages, they must be regarded in the most serious light, and, in view of the wonderful conservative and recuperative power of the vital principle, it may well be asked, How far should the accoucheur go under the contingencies involved, and when should he avoid or desist from processes which occasion only in very small degree a further loss of blood?—for we are here to remember that it was the last pound that broke the camel's back. That the determination of a question of such gravity and importance should have so often been attempted in earlier and recent times without decided success is not surprising; nor, in fact, need we wonder at the variety or antagonism of opinions upon this subject, involved as it is in difficulties and contingencies of no ordinary character. In the cases and under the conditions presented, a large majority of practitioners would at the present day resort to an active mode of treatment, for this is in accord with the current teaching; and again, many might not, in case they anticipated the loss of the patient, be willing that she should depart otherwise than *secundum artem*; whilst a smaller number, more conservative in medical thought and practice, might, under similar conditions, prefer that her departure should be *secundum naturam*. To attempt to define the precise line of conduct to pursue in the emergency referred to, or to declare what should and what should not be done in the critical conditions in view, is not only impracticable but would be hazardous; for, however similar the general conditions of a large majority of such cases may appear, there will of necessity be modifying circumstances, and unless these be rightly and promptly appreciated we incur the risk of endangering the slight hold upon life the woman yet retains; for it is beyond question that in the crises alluded to the loss or the preservation of a few ounces

of blood may decide the fate of the patient. In view, then, of the danger the parturient woman is so often exposed to from hemorrhage, it is the duty of the practitioner faithfully to record every circumstance, however minute, occurring in the dangerous, but more especially in the fatal, cases he may have had in charge; for it is not by theory, but by gathering together and collating a numerous series of well-established facts regarding this subject, that a more successful mode of treatment can be arrived at.

In this connection reference may here be made to the actual doctrine and practice in regard to the delivery of the placenta in ordinary labor. As a rule, it is now recommended that little if any delay should be permitted before proceeding actively to the removal of the after-birth, so as to afford opportunity for contraction of the uterus, which, as is commonly said, cannot take place while the placenta remains undelivered, and the woman is thereby exposed to the danger of hemorrhage. The rule of action, and the propositions here announced, may be accepted in general terms; yet this mode of treatment, and the propositions on which it is founded, will very often be at fault, and do not accord with the views or experience of the most eminent authorities of earlier times. In my own experience it has very often happened that the placenta has remained in an uncontracted uterus many hours—on one occasion for thirty-six hours—without injurious result; and in not a few cases, where the placenta, either spontaneously or by active interference, was expelled promptly after the birth, the flow of blood still continued until the patient was greatly exhausted, and in these cases it is probable the blood issued from one or more vessels of preternatural size. In regard to the relaxation and rising of the uterus after it has contracted well, we have not, as a rule, observed much increase in the flow, especially if the previous discharge has been moderate; where the reverse has occurred, it has nearly always been in women of a constitutional predisposition to hemorrhage. In every instance where the uterus rises towards the abdominal region a careful local examination should be made, and attention given to the pulse, to ascertain whether the case is one of concealed hemorrhage or one of mere relaxation.

When called, for the first time, to a woman in labor, it is best, in order to prepare for an emergency, to inquire whether, in previous labors, she habitually or occasionally suffered from great loss of blood; and whether this had occurred before or directly after the expulsion of the placenta or, again, as may happen, not until an hour or two afterwards: in the latter case the accoucheur should remain at least a corresponding length of time, that prompt aid may be given if required. The difference between women, in regard to their ability to support great loss of blood, varies immensely, and cannot always be determined by the ordinary external signs of fulness of blood and strength. In the earlier days of my practice in the country (and those were the days of venesection), when the city physician often, and the country physician always, had to perform the operation, it frequently happened that the robust, ruddy-faced farmer or laborer would show symptoms of faintness before ten ounces of blood had been drawn, whilst a meagre-looking, pale-faced man or woman would bear the loss of fourteen to sixteen ounces without inconvenience. The same thing occurs in obstetric practice: so that the hemorrhage which would endanger or destroy the life of one woman might be borne perfectly well by another of no apparent greater physical strength.

ANTHRACÆMIA—WOOL-SORTER'S DISEASE.

Read before the Philadelphia County Medical Society, October 13, 1880,

BY WILLIAM R. D. BLACKWOOD, M.D.,
Attending Physician to St. Mary's Hospital.

FOR several years past the attention of our professional friends in England has been attracted to a serious form of sickness prevailing to a considerable degree among operatives employed in woollen-mills, the study of which has notably been made a point by Dr. Bell and gentlemen practising near Bradford. Some months ago a committee was appointed by the Medico-Chirurgical Society of that city to investigate the matter, and recently four typical cases have been reported in which the result of post-mortem examination leaves no room seemingly for doubt as to the existence of this peculiar affection, and that in all probability it is due to blood-poisoning by the so-called *Bacillus anthracis*, a low form of bacteria, pre-

sumably contaminating the wool, and which gains entrance to the blood of those affected through the likeliest channels,—the lungs or stomach. Wool from which yarn of varying character is made, and which is used in whole or in part in the production of a long line of textile fabrics, is gathered from the ends of the earth, and when received is frequently very dirty, the Continental grades being especially impure. The ordinary method of sheep-washing previous to shearing is more of a habit than a success, and consequently, before the process of manufacture into yarn, wool has to be thoroughly scoured after reception at the mills, either by hand or by machinery. The impurities found in the fleece consist largely of earthy or vegetable matter, depending on the nature of the pasturage and shelter of the flock; but there is also at times animal matter,—the "tick," for example,—with scales or scabs from the epidermis of the sheep, together with more or less oily material. Diseased sheep or goats may be rejected as unfit for food, but the wool or hair is all the same secured for market. Now, before scouring the wool is "sorted" into long or short fibre, fine or coarse, etc., quality of stock determining largely the ultimate product. This is done by hand in well-lighted rooms which are kept at a high temperature, especially in the cooler months, and it is here that the majority of cases of anthracæmia originate; but some have happened in operatives exposed only in departments after the material has been scoured, in which condition it is usually clean and white. A much better method is being tried, by which before sorting the wool is treated with benzine, which not only cleans it of dirt but also must destroy all bacteria. The caution requisite in this process and the high insurance unfortunately operate against the plan, but time and necessity will doubtless remedy these disadvantages.

The symptoms so far recognized are violent cephalalgia, often unilateral, fever intensifying in its progress, severe pleuritic pain, crepitant inspiratory rales, and finally free diarrhœa. The differential diagnosis between anthracæmia and typhoid fever is clear, and ordinary care only is requisite to distinguish them. Cases have been complicated with malignant pustule from inoculation by scratching pimples or abrasions, especially about the face, and in such instances the neighboring lymphatics have become greatly enlarged. The prognosis is bad, and treatment is, as yet, apparently unsettled.

Post-mortem investigation shows softening of the bronchial glands and large accumulation of fluid in the pleural cavity particularly, but also in the abdominal. The intestines, beyond injection and low inflammatory signs, give no evidence. The glands of Peyer are not softened or ulcerated. *Bacillus* is abundant in the fluids of the closed cavities, in the viscera, and in the blood. Inoculation of blood containing this form of bacteria in the lower animals, as tested in the mouse, rabbit, and guinea-pig, produces the disease, death supervening in from thirty-six to seventy-two hours. Decomposition is rapid, especially at the site of puncture in the case of inoculation.

My attention was called to this subject from having during the summer treated two obscure cases of illness in wool-sorters resembling very much the affection described, and which, though they recovered, induce me to refer to them with a view to further investigation by gentlemen of the Society who may have an interest in the subject. Their sickness was precisely as above described. The period of incubation, so far as known, was about ten days, the acute duration two weeks, and as much more time for convalescence was required. The treatment was expectant,—large doses of cinchonidia sulphate for the bronchial disorder; opium and carbolic acid for the diarrhœa; tincture of iodine painted externally for the pleuritic pain. There was no tendency to a relapse. Another patient (a driver), who handled bales of wool continually, succumbed after leaving my care from what was certified as phthisis, but which very likely was anthracæmia. Under the circumstances, I was debarred from suggesting a post-mortem. Through the courtesy of my brother, Mr. James D. Blackwood, who is engaged in the manufacture of woollen and worsted yarn, I have examined a great variety of wool, domestic and imported, and also the residue left after scouring. The high temperature and caustic soaps and alkalies employed in washing destroy all traces of bacteria, if they exist in the wool before undergoing that process, and, although cold water in which wool has been thoroughly soaked frequently contains

these organisms, I am not yet satisfied as to the origin of them, neither have I been able to obtain accurate information as to the *Bacillus anthracis* other than from allusions to it in the English medical journals, but I hope to be better posted shortly through friends who are interested in the subject in England. I learn from my brother that, aside from domestic supply in our city, foreign wool is imported only of English growth and from Australia, all of which being comparatively clean may account for the non-appearance of anthracæmia in this country as yet. The supply from Persia, Algiers, and Barbary is exceedingly foul, but to his knowledge is unknown in America, although large quantities of these grades are handled abroad. In view, however, of the extent and increasing business in woollen production in this country, and the probable development of this disease as a sequence through a greater demand for foreign material, it becomes our duty and our interest to unravel any entanglement which may confound anthracæmia with obscure disorders in those exposed thereto, and isolate this intruder if it be an entity, in preference to looking upon anomalous diseases in these people as hybrid,—a condition which I for one do not believe exists in pathology.

246 North Twentieth Street.

A SPORADIC CASE OF HOSPITAL GANGRENE.

BY J. H. POOLEY, M.D.,

Lecturer on Surgery in the Columbus (Ohio) Medical College.

AUGUST 12, 1880, I was asked by Dr. Schueller to see in consultation with him F. B., a boy aged 10 years, who a short time before had received an injury from the wheel of a street-car passing over his right foot; and as the injury was a severe one, and the case involved grave responsibility, the doctor was good enough to ask my co-operation in the treatment, so that I had the opportunity of carefully observing it throughout.

The wound, which was a deep and much lacerated one, passed along the inner border of the foot from the toes to the heel, almost in a straight line. The skin and soft parts generally were extensively dissected from the sole of the foot, and the metatarsal bones comminuted to some extent. About the ankle the integument was superficially torn, and turned back to the extent of about two inches; the joint was entirely uninjured. There was but little hemorrhage. After careful examination, an attempt to save the foot was deemed feasible. The wound was carefully cleansed, some loose pieces of bone removed, and the edges brought together loosely by a few points of interrupted suture. To forestall inflammation, we made use of Petigaud's mediate irrigation, by means of the india-rubber coil, through which cool water was passed, the foot being protected from too great an impression of cold by means of a roller bandage. All went on very well at first; inflammation was kept down, and the patient had little pain. After three or four days, however, it was evident that considerable sloughing was going on; the apparatus was removed, and warm lotions of carbolic acid were substituted, to favor the separation of the sloughs. But the gangrene spread, not only in the deeper portions of the wound, where it had the ordinary appearance of mortification after injury, but also in that superficial wound over the ankle, already alluded to, where it had the appearance of hospital gangrene, a thing I had not seen since our late war, now sixteen years ago.

The surface was covered over with a light-grayish, tenacious, greasy-looking deposit, which could not be washed or wiped away. The edges were thickened, infiltrated, and somewhat everted. The boy had a good deal of pain, at times very severe. The pulse was frequent, 120; there was irregular fever, with profuse perspiration and utter loss of appetite; tongue much furred; obstinate constipation.

It was now pretty evident that the attempt to save the foot would be useless, if not hazardous, and with the concurrence of Dr. Wirth, who was called in consultation, the leg was amputated a short distance above the ankle, by the circular method, on Saturday, August 21.

The next morning I found the stump painful, swollen, the edges everted and pouting between the sutures, and covered with a whitish-gray film of exudation. The discharge was thin, ichorous, rather free, and of a peculiar, penetrating odor. The boy had had a bad night, and his condition was the same as before the operation.

The stitches were removed, and the whole interior seen to be covered with the partly whitish exudation already described. Strong carbolic acid lotion was applied to the stump, the interior of which was syringed out with the same.

Quinine, iron, and stimulants, which the patient had already been ordered, were continued.

The gangrene continued for several days, the exudation appearing to increase in density, and numerous sloughs of connective tissue came away. The skin remained unimplicated throughout. A strong alcoholic lotion, with carbolic acid, was now ordered, and almost

at once a change for the better was discernible; healthy granulations began to spring up; the remaining sloughs were cast off, and in a week we were able to begin to close the stump with adhesive straps, and it healed very rapidly, together with which the general health of the patient improved, so that in three weeks he was able to go out.

The disease of which this is a sporadic example is very rarely seen except in an epidemic or endemic form, so that I have thought it well worthy of record and preservation.

The name hospital gangrene, by which it is best known, is certainly inapplicable to such a case, nor is it easy to find in its somewhat extensive synonymy a designation that is perfectly unexceptionable. It has been called gangræna contagiosa, phagedæna gangrænosa, gangræna nosocomialis, putrid ulcer, pulpy gangrene, pourriture d'hôpital, hospital brand, putrid degeneration, traumatic typhus, and diphtheria of wounds.

Of these names the most misleading is sloughing phagedæna, as I believe it to be entirely distinct from phagedæna, though resembling it in some of its features. The term diphtheria of wounds is also objectionable, as tending to confound this disease with another well-known constitutional affection. It is, however, a favorite designation with the Germans, and by them is often very loosely applied. Hospital gangrene in its epidemic forms is both infectious and contagious: whether in our case it was so or not, fortunately there were no means of deciding. It has been said that sporadic cases are owing to some peculiar defect of constitution in the patient, but, so far as we can tell, this boy was in perfect health at the time of his injury; and also that they are more apt to occur during the prevalence of erysipelas, scarlatina, diphtheria, etc., but, so far as I know, no disease of the kind was prevailing here at the time.

That this was really a case of hospital gangrene seems evident, I think, from the following considerations: the suddenness with which it made its appearance in the stump after amputation; the operation was done through healthy tissue, so that, although there was purulent infiltration just below, the fine, healthy appearance of the muscles at the point of amputation was a matter of remark to us at the time. And yet the next morning, less than twenty-four hours afterwards, we find the disease fully set in in the stump. This is very characteristic, and, together with the peculiar deposit alluded to, and the general *ensemble* of symptoms, settles the diagnosis. The case was indeed very mild, far different from the terrific and rapidly-destructive course of the epidemic form; but this mildness of sporadic cases has before been commented on.

The peculiar diphtheroid deposit of this disease bears, after all, but a feeble resemblance to that of true diphtheria, lacking altogether its thickness, tenacity, and capability of being detached in plates or extensive pieces.

It consists, according to Dr. W. Thomson, who examined it microscopically, mainly of fluid granular matter and débris; no evidence of textural growth was found in it, and no organisms. According to Professor Joseph Jones, and some German observers, both animal and vegetable organisms have been found, but there is no sufficient reason for believing that they have any causal relations to the disease. To illustrate the rarity of sporadic hospital gangrene, I have collected the following statements from various writers, which I present with the remark that the majority of the authorities examined say nothing about it.

Agnew says (Surgery, vol. i. p. 139), "It may prevail in two forms, the endemic and the sporadic. In the second, the disease appears to be confined to isolated cases and sores of a specific nature, as chancre and open cancer" (which is true of phagedæna, but not of hospital gangrene, properly so called). Spence speaks of it (Lectures, vol. i. p. 68) as gray pultaceous phagedæna, and says, "Occasionally we meet with sporadic cases, depending either on some unhealthy tendency in the individual, want of cleanliness, or from improper, irritating dressings having been used, most likely from a combination of all these conditions; but by far the largest number and best-marked cases arise either from endemic or epidemic influences." Miller says (Principles of Surgery, p. 345), "It seems to have been known and described by the old writers, as Aetius, Paulus, and Avicenna, but was not noticed prominently and distinctly until the end of the last century and beginning of the present." He makes no reference to its sporadic occurrence. Erichsen (Surgery, vol. i. p. 580) says it is rarely met with in its fullest

extent, except in military practice, and makes no mention of sporadic cases. Gant says (Surgery, p. 216), "Hospital gangrene is fortunately known to but few surgeons in civil practice now living; and we must refer to those of the past for information." Bryant says (Surgery, p. 436), "In its sporadic form it seems especially to affect the subjects of septic or pyemic disease, and perhaps the existence of certain conditions of the secretions inclined to coagulation may favor its production." Ashhurst says (Surgery, p. 392), "This affection is occasionally met with as a sporadic disease, but has attracted most attention when prevailing epidemically or endemically in hospitals, especially when large numbers of wounded men are crowded together, as in military hospitals in the neighborhood of a battle-field." Fergusson says (Practical Surgery, p. 99), "Such a disease as that once familiarly known under the name of hospital gangrene is now rarely seen, although from time to time, both in hospitals and in private, cases are met with which resemble in many respects those of former years."

THE MODE OF PRODUCTION OF ARTERIAL HYPERTROPHY AND ATHEROMA IN BRIGHT'S DISEASE AND ALLIED CONDITIONS.

BY JOHN S. WOODSIDE, M.D.,

Assistant Physician King's County Insane Asylum, Flatbush, L.I.

I HAVE had the subject-matter of this paper under consideration for the past year, while studying Bright's disease as it occurs among the insane, and have arrived at conclusions in regard to the production of the hypertrophy similar to those advocated by Da Costa and Longstreth in their valuable and original investigations into the "state of the ganglionic centres in Bright's disease."*

It is for the purpose of supporting their views, and of further disseminating and elucidating the subject, that the following remarks are offered. They "point out the causal relations which they believe the muscular hypertrophy of the vessels has to the alterations found in the ganglia," and they arrive at two chief factors of irritation which bring about the hypertrophy:

First, that "the cause may be of such a nature that it operates through the general nervous system, for it is a well-ascertained fact that grief and sorrow and nervous depression are potent sources of Bright's disease, especially of the contracting kidney." Enough stress has not been laid on the frequency, extent, and etiological power of this psychological irritation. It is corroborated and beautifully exemplified among the insane, particularly in chronic cases. Out of about fifty autopsies made at this asylum during the past two years, only three or four had what would be pronounced healthy kidneys. The arterial changes, however, were always well marked, even when but a slight amount of renal disease was present. In going through the wards of any asylum, it is interesting to note how many of the cases present the full, tense pulse, giving that peculiar resistance to the finger which indicates thickening of the arterial coats and general vascular changes.

Secondly, "the disturbance may come through the blood, for the nutrient fluid supplying the renal plexus, if altered, will produce a condition of irritation of the ganglionic cells, with subsequent tissue-changes alike in the ganglia and in the kidneys, and give rise to the phenomena of intestinal nephritis,—hyperplasia of the connective tissue and hypertrophy of the vessels." (Da Costa and Longstreth.)

Dr. George Johnston, who was the first to elucidate, and who continues to defend, the fact that cardiac and arterial hypertrophy invariably follow chronic kidney disease, explains the mode of its production by reflex action, and likens the "excessive arterial contraction excited by an abnormal quality of blood, as analogous to spasm of the glottis provoked by an irritating gas or foreign body in the larynx." This is not a good parallelism, however, as the reflex is undoubtedly through the sympathetic, and, like all sympathetic reflexes, slow and persistent in character, and unlike the quick, transient cerebro-spinal reflex exhibited by the glottis.

The character of the sympathetic reflex is best exemplified by the movements of the pupil. In going from darkness to a brilliantly-lighted room, it is some time before the irritation carried by the optics to the corpora quadrigemina, and reflected along the oculo-motorius to the ophthalmic ganglion, and thence by the ciliary nerves

* American Journal of the Medical Sciences, July, 1880.

to produce the requisite contraction of the pupil, takes place; but when the contraction is complete, *it remains so until the provoking stimulus is removed.* So it is with the arterial reflex which I am about to describe.

Gull and Sutton deny the hypertrophy of the muscular coat, and describe a condition of the vessels which they designate "arterio-capillary fibrosis," and express their belief that the "cardio-vascular changes and renal degeneration are the result of this morbid state, which is allied to senile degeneration," considering Johnston's hypertrophy "a hyalin-fibroid change."* The weight of further investigation goes to support Johnston's observations in the main, yet undoubtedly demonstrating secondary changes in the surrounding connective tissues.

The following I take to be Da Costa and Longstreth's theory, *in extenso*, which harmonizes the above facts, and renders clear the sequence of events which commences with blood-deterioration and winds up with vascular transformations and connective-tissue degenerations.

The action of the intracardial ganglia and the intestinal gangliated plexuses of Auerbach and Meissner is now well understood. Vulpian, Hénocque, Klebs, and Arnold agree in the following analogous mode of termination of the vaso-motor nerves in the arteries: a fundamental plexus distributed outside the external tunic; an intermediate plexus situated in the external tunic, and composed of filaments from the fundamental plexus; an intermuscular plexus, excessively delicate, which comes from the intermediate plexus, and which terminates in punctiform enlargements, sometimes in the nucleus, sometimes in the fibre, and sometimes in the interstices between the fibre-cells. Small ganglia are found on all of these plexuses, particularly at the bifurcations and points of anastomosis, and, also, nodular enlargements are found in the course of the finest filaments.

The efferent fibres of these minute ganglia which are distributed to the intima, being irritated by the passing impurities, carry an excessive amount of stimulation to the ganglia just described, which causes them to evolve and transmit an excessive amount of nervous energy by their efferent fibres to the muscular coat, causing a *persistent* contraction and consequent obstruction of the blood-current; this in turn calls forth increased cardiac action with its resultant hypertrophy. The irritation continuing, contraction is sustained, giving rise to the arterial hypertrophy, and interfering with the blood-supply of the vasa vasorum to the intima, which consequently undergoes fatty degeneration or atheroma. This, in turn, spreading from the larger arteries to the arterioles, and finally to the capillaries, interferes with the normal supply of nutriment to the tissues, as well as with the reception of the waste nitrogenous matters. This condition continuing for weeks and months leaves the body cachectic, and a fit nidus for general somatic degenerations, which are most likely to occur in the connective-tissue elements. The irritated ganglia undergo granular degeneration, with hyperplasia of their connective tissue.

GLYCYRRHIZA AS A CORRIGENT.

BY E. T. BLACKWELL, M.D.

THE taste of common liquorice is very agreeable to a considerable portion of the human race. The stick is greedily devoured by children, while the juice in many countries is a favorite drink. Its quality of correcting unpleasant medicines has been utilized somewhat, but its usefulness in this particular may be greatly extended. The fluid extract masks so completely the cinchona salts as to render them acceptable to children and other persons of fastidious taste. A very limited amount of acid only is allowable to facilitate the solution of the salt, as any excess precipitates the glycyrrhizin. Made carefully and lightly shaken, it forms a very good mixture.

The fluid extract may be included in a multitude of combinations, embracing solutions of morphine and chloral, as also diarrhœal and cough mixtures, tonics, etc. An example or two may suffice:

℞ Ext. rhamni purshianæ fl.,
Ext. glycyrrhizæ fl., āā ℥ij;
Aq., ℥j.—M.

S.—A teaspoonful to be given at night, to be repeated p. r. n.

℞ Chloralis, ℥ss;
Ext. glycyrrhizæ fl., ℥ij;
Aq., ℥iss.—M.

S.—Give a teaspoonful, and repeat p. r. n.

A remedy of extended popularity is the pulvis glycyrrhizæ compositus of the Prussian Pharmacopœia. The formula is exhibited to show the proportion of each ingredient in a teaspoonful, the usual dose prescribed:

Pulv. Glycyrrhizæ Comp., Pr.

	In each teaspoonful.
℞ Glycyrrhizæ pulv.,	6 grains;
Sennæ pulv., āā ʒj,	6 "
Sulphur. loti,	3 "
Fœniculi pulv., āā ʒss,	3 "
Sacchari albi, ʒiij,	18 "
M.	—

Amount, 36 grains,—containing 9 grains of laxative and 27 grains of excipient, a proportion of 1 to 3.

This prescription is faulty not only in that it is weak in laxative power, but because of the very great amount of sugar, which increases fermentation in sour stomachs, rendering it very objectionable in many cases. Its form is inexact, because an article affecting the combination as a corrigent is taken from its legitimate place, at the foot of the formula, and placed at its head. That it should give name to the medicine is absurd, for the same reason.

The British form, which omits the sulphur and fennel, perpetuates the misnomer, notwithstanding it degrades the naming article from the head of the recipe, which is here displayed for the reason already given:

Pulv. Glycyrrhizæ Comp., Br.

	In each teaspoonful.
℞ Sennæ pulv.,	8 grains;
Glycyrrhizæ pulv., āā ʒij,	8 "
Sacch. alb., ʒvj,	24 "
M.	—

Whole amount, 40 grains,—laxative matter 8 grains, excipient 32 grains, or a proportion of 1 to 4.

The following scheme, in which the remedial drugs occupy the leading place and the corrigents and demulcents their appropriate relation and amount, I propose, with the name of pulvis sennæ compositus, as a substitute for the forementioned. The benefit of alliteration is used to aid the memory:

	In each teaspoonful.
℞ Sennæ pulv.,	8 grains;
Sulphur. loti,	8 "
Sacchari albi, āā ʒss,	8 "
Fœniculi pulv.,	4 "
Glycyrrhizæ pulv., āā ʒij,	4 "
M.	—

In all, 32 grains,—laxative 16 grains, excipient 16 grains,—an equal proportion.

No one will question, I think, the improvement in bringing the quantity of sulphur to equal that of the senna, which it so much surpasses as a laxative. Nor does it prove less acceptable to the taste, while it is better tolerated by the stomach.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

CLINICAL SERVICE OF R. J. LEVIS, M.D.

Reported by CHAS. H. WILLITS, M.D.

NOTES OF A CASE OF TRAUMATIC HERNIA THROUGH THE DIAPHRAGM—CASE OF FRACTURE OF VERTEBRÆ, WITH TREATMENT AND GENERAL REMARKS.

GENTLEMEN,—The following history, kindly furnished by Dr. Croll, resident surgeon, is one of great interest and rarity:

C. L., a German, 37 years old, was brought to this hospital about 3 A.M. He was injured in a sugar refinery by a bar of iron eighteen inches long and five pounds in weight, which had been violently hurled from a centrifugal machine, striking him. His condition was low, skin cold and clammy, pulse feeble and accelerated. His respirations were short, shallow, and frequent, and accompanied by a "wind-and-water" sound, and by the expulsion of frothy blood from the wound. His temperature was ninety-seven and two-fifths, and he was very restless, evidently suffering considerable pain.

Upon examination, a wound, four inches long, in the left infra-mammary region was found, through which a mass of omentum, the size of a man's fist, protruded.

Further examination revealed a fracture of the seventh and eighth ribs and a lacerated wound of the diaphragm two and a half inches long, about one inch from its origin from the chest-wall, and almost parallel with it.

If the fingers were placed in the wound, the heart could be felt beating.

The omentum was returned, and the external wound closed by adhesive straps, allowing for free drainage at the dependent part.

Beef-tea and milk-punch were ordered, one-quarter of a grain of morphia was given hypodermically, and hot applications, as bottles of hot water, and blankets, were placed around him.

The man's condition being no worse at noon of the same day, I decided to stitch up the wound in the diaphragm, which I did with fine silver sutures, the ends of which were brought through the external wound. This latter itself was stitched, and drainage and dressing of carbolized lint used as before.

The patient was more or less restless throughout the day, and considerable frothy blood passed away. His condition remained about the same until evening, when there was a change for the worse, his pulse and respiration becoming more feeble and frequent.

His restlessness was controlled by morphia, and his stimulants increased, but, notwithstanding all care, he died about 11 P.M.

A post-mortem examination showed, in addition to the above, a lacerated wound one inch long, in the extreme lower edge of the lung, with several small, superficial patches of collapsed lung in the posterior part of the lower lobe, and also about one pint of frothy blood in the pleural cavity.

I shall now bring before you one of those grave cases often met with in this hospital, which are peculiarly liable to occur in the mining-regions. I refer to fracture of the vertebræ.

Fracture of the spine is due, as in fracture of other bones, *first*, to *direct violence*, as a fall directly upon the vertebræ, or in the case of a heavy weight, as a wagon-wheel or heavy brick wall, acting upon the seat of injury; *secondly*, to *indirect violence*, as when a man falls from a height upon his feet, the force necessary for the fracture being communicated through the limbs, or, when he falls upon his head, the force being transmitted through the column itself.

Another factor that should always be remembered in these cases is, that the spine may be broken through *extreme flexion*.

A good example of this is found in the case of a man working in a well, in a necessarily bent position. If at such a time the wall should fall in upon him, the chest would be forced down upon his knees, and the vertebræ so forcibly flexed as to bring about fracture.

The spinal column may be broken in any of its parts, either through the bodies of the vertebræ, their spines, or their arches. Perhaps the most common seat is the arches.

The gravity of the injury is due to the violence done to the contained substance, the spinal cord, and the cutting off of the nervous supply to important organs. Thus, a fracture as high up as the third cervical vertebra is excessively grave, involving as it does the phrenic nerve, the great motor nerve of the diaphragm.

The most common seat of fractures of the spine, I may say, is between the last dorsal and the first lumbar vertebra.

I have said that extreme flexion is an important factor in this injury; and, as the point of greatest anterior flexibility of the column is near the last dorsal vertebra, you can see in this a reason for the frequency of fracture at that point.

I would say here that, owing to the peculiar manner in which the vertebræ are articulated, there being so much interlocking, dislocation without fracture can hardly exist.

In most cases of fracture of the spine you have general paralysis below the point of injury; thus, if at the last dorsal, it would interfere with respiration somewhat by paralyzing the muscles of the abdomen, and would also, lower down, involve the bladder and rectum.

This last symptom is a most important diagnostic point, no matter at what point the fracture may exist.

As a rule, there is retention of the urine for the first few days, followed by constant dribbling, and usually, also, constipation, succeeded by involuntary evacuation of fæces.

In regard to treatment, there is scarcely any mechanical treatment possible. Of course, if you could readily determine any displacement of the fragments, you would be justified in using some means, as extension and counter-extension, to remove it; but this is scarcely ever needed.

Our attention should rather be directed to the secondary symptoms, such as the

results of the paralysis of the bladder and rectum, than to the primary lesion.

The first, and I think the most important, point requiring remembrance is the fact that these patients incur great danger from the formation of bed-sores, resulting either from pressure upon prominent parts of the body, as the nates, calves, and heels, or from the irritation of the constantly dribbling urine.

This condition, when present, you will find exceedingly troublesome to cure, as well as very dangerous to the patient.

The avoidance of this complication can be best accomplished by the use of the water-bed, if that commodity can be possibly obtained. This, you will find, will equalize the pressure and adjust itself nicely to all the curvatures and irregularities of the body.

Of course, such a convenience, which, you know, is merely a rubber sack filled with water, cannot always be readily obtained; if such be the case, a good substitute can be made with a simple wooden trough, large enough to admit the whole body, and filled with water, over which is stretched a rubber cloth.

In directing your attention to the bladder, you will not only be obliged to draw off the urine, but, as it often becomes highly phosphatic, or even putrid, it is a good plan after the bladder is emptied to wash it out thoroughly with a saturated solution of boracic acid, or a weak solution of carbolic acid.

Our patient, whom I now bring before you, was working at the elevated railroad, where a heavy wall fell upon him, producing a manifest fracture of the spine.

The bone thought to be broken is in the lower dorsal region; but we will not disturb our patient with further investigation.

His symptoms are the usual ones, namely, total paralysis up to the point of lesion, pain and redness at that point, involuntary evacuations, and incontinence of urine.

You see he is floated upon the all-important water-bed, thus guarding all salient points from pressure, and a vessel is kept constantly in position to catch the dribbling urine.

This, with attention to his diet and cleanliness, will make our patient as comfortable as his condition will admit.

TRANSLATIONS.

PHYSIOLOGICAL ACTION OF PILOCARPIN.—Dr. Albertoni publishes an elaborate essay on this subject in the *Giornale la Saluta*. He first speaks of the general effects of the drug, giving the account of an experiment made by a Dr. Wontonini, who says,—

"I took sixteen grammes of jaborandi leaves in two hundred grammes of water, the infusion being yet warm. I was suffering from an attack of acute rheumatism. Just one minute after having taken the infusion, which I took in a single dose, I felt my skin covered with a profuse perspiration.

"While I was sweating profusely, my salivation commenced, with at the same time great difficulty of respiration. At this period vomiting came on, and I rejected a great part of the infusion. After this attack of vomiting I did not feel relieved, and still experienced the desire to vomit.

"The salivation and perspiration continued, so that I felt as if I were surrounded by a zone of steam.

"Half an hour after the ingestion of the medicine I was the subject of hallucinations. Looking at a single candle with a single flame, it appeared to me as if composed of *seven* or *eight* different flames, each being of much greater dimensions than the original.

"At times I imagined myself attacked by wolves and bears, and heard also, as if at a remote distance, sounds resembling those heard on a battle-field. These phenomena lasted for three hours, during which I felt very near death. My rheumatism persisted notwithstanding my tremendous sweating."

On Dogs.—In dogs poisoned with pilocarpin the respiration, at the beginning not modified, grows less frequent and more difficult, and a great degree of dyspnœa may supervene. With the occurrence of dyspnœa the pupil, until then contracted, dilates. Death is preceded by muscular tremors or generally by paralysis,—more rarely by convulsions or loss of sensibility or of consciousness. Death occurs ten hours or longer after the hypodermic injection of the largest lethal dose.

The fatal dose is one centigramme for each kilogramme of body-weight.

Action on the Nervous System.—The pilocarpin has not a direct influence on the encephalon. The cephalalgia and the mental depression are to be largely attributed to the vomiting, salivation, and vascular modification.

In a dog some moments before death attacks of convulsions were noticed, particularly tonic cramps of the limbs. But, as the heart's action was very feeble and the brachial pulse could not be felt, it was inferred that the convulsions were due to anæmia. And these convulsions were almost always present when the medicine was injected in a vein. Also, therapeutic doses produce modification in the cerebral circulation. As an example the following may be cited. In an old dog weighing eight kilogrammes, Dr. Albertoni exposed the circulation in the right temporal region, and then injected into the animal fifteen milligrammes of the salt. Five minutes passed, when saliva commenced to flow, and then the cerebral cortex became more and more rosy and the vessels larger. After a quarter of an hour the hyperæmia vanished and anæmia took its place. The cardiac action then greatly diminished, becoming feebler and feebler at every moment. When emesis commenced the anæmia became more prominent. We can see from this that the mental depression is due to anæmia of the encephalon. In warm-blooded animals, as well as in cold-blooded, if a large dose of pilocarpin was administered a diminution of excitability of the motor nerves and an irritability of the striated muscular fibres were witnessed.

Circulatory System.—Colland and Rabow assert that the injection of one or two centigrammes after the lapse of two or three minutes produces in man an increase in the pulse-rate of ten to thirty beats per minute, diminishing the arterial pressure. Later, when the flush is replaced by pallor, the frequency of the pulse is still less. Leyden affirms that in man a medicinal dose dilates the arteries and veins, the pulse becoming more frequent and stronger, and dicrotic and subdicrotic. The sphygmograph shows, as demonstrated by Kahler and Seyka, that jaborandi produces stasis of the blood-vessels. By small doses of the medicine augmentation of the frequency of the pulse and a moderate lessening of arterial pressure are obtained; by somewhat larger doses, diminution of the pulse-rate to thirty or thirty-two pulsations per minute and moderate augmentation of the arterial pressure; by still larger doses, diminution of arterial pressure and retardation of the pulse-rate to eight or ten beats per minute. This is attributed by Leyden to the stimulation by the drug of the intracordiac fibres of the pneumogastric, and not to stimulation of the heart itself.

In Dr. Albertoni's experiments, retardation of the pulse was more prominent in dogs than in cats and rabbits. There are two stages capable of notation in the dog's pulse after the injection of pilocarpin,—first, acceleration; secondly, retardation. With medicinal doses the retardation of the pulse is slight, with fatal doses it is great and persistent.

In all his experiments Dr. Albertoni found that pilocarpin reduces the arterial pressure, which is due to anæmic irritation of the nervous centres, explained by the destitution of blood in them. The action of pilocarpin is not confined to the heart alone, but is extended to all the circulatory system. When in the frog the lymphatic ganglia are examined, they are found to be affected *pari passu* with the circulatory apparatus. The primary acceleration of the pulse is partly due to stimulation of the excito-motor apparatus of the heart.

Respiration.—Acceleration of respiration always takes place when a fatal dose of the drug is injected. *Pari passu* with the retardation of the pulse respiration augments in acceleration, reaching the point of intense dyspnœa, which ceases with the last movement of death. Such dyspnœa depends,—first, on the influence of the circulation; secondly, on the accumulation of secretion in the respiratory tract; and, thirdly, on œdema of the organs of respiration.

Temperature.—In man, in medicinal doses, in the second stage, and after the profuse perspiration, a slight lowering of temperature occurs, and this persists until death.

Secretion. — The salivary glands are greatly affected by the drug. Dr. Albertoni found that one centigramme of the pure alkaloid augmented greatly the secretion during the first hour. After this the secretion diminished, but lasted for nearly two hours. The quantity secreted in that time was from two hundred and ten to two hundred and eighty grammes,

being neutral and containing sulphocyanuria.

Lewin asserts that in his recent experiments, 0.015 gr. of pilocarpin excited two hundred and eighty cubic centimetres of secretion.

A larger dose excites a less quantity of saliva, but much more dense, and especially so when vomiting supervenes together with diarrhœa.

Like Langley and Nawrocki, Dr. Albertoni observed that pilocarpin produces, just after the destruction of the secretory nerves, a copious salivation of the submaxillary glands. It appears probable that salivation depends upon excitation of the glandular secretory nerve-endings.

Dr. Albertoni repeated the experiments of Luchsinger and Nawrocki in cats and dogs, consisting in the section of the sciatic nerve, and after the operation a profuse sweating of the corresponding leg occurred.

In new-born cats pilocarpin produces salivation, but not perspiration.

Antagonism and Antidotism of Pilocarpin and Atropin.—Dr. Albertoni's experiments prove that an animal to which a fatal dose of jaborandi has been given may be saved by the proper administration of atropin. I administered both hypodermically, and when the retardation of the pulse had reached its maximum. A few minutes only were necessary to bring the pulse from twenty or twenty-five to one hundred, and the vomiting and diarrhœa promptly disappeared. P. Bétancourt.

Treatment of Lupus Vulgaris.—E. Schiff (*Vierteljahresschr. für Derm. u. Syph.*, 1880, p. 247) draws attention to the valuable but too little known contribution of Auspitz on the mechanical treatment of skin diseases, published in the same journal in 1876. Auspitz recommended, in place of the old method of cauterizing the lupus nodules with caustic potassa, that the sharp spoon or curette of Volkmann should be employed, either alone or in connection with the caustic. In addition, Auspitz recommended multiple puncture by Volkmann's method, and described a combination of the curette with a needle by which the desired end could be the more easily attained. Auspitz, however, confessed his procedure not altogether satisfactory, and suggested that the following method should be followed. The sharp point of the needle attached to the back of the spoon is first dipped in a solution of one part of iodine in twenty of glycerin, and then thrust into the lupus nodules. This process works very well, and in some cases with surprising success. But Schiff has recently devised a better method. For it will be found on trial that the continual dipping of the needle into the caustic fluid is a tiresome business, on the one hand, and, on the other, the very act of thrusting the needle into the tissues wipes off a large part of the fluid, which is thus lost. To obviate this difficulty Schiff has devised a sort of needle pipette, the point of which is hollow and sharp, like that of a hypodermic syringe, and to which is attached a hollow india-rubber ball. The whole instrument is not unlike the dropper used by ophthalmologists. It is evident that by this means a drop of the caustic fluid can be introduced without difficulty into the middle of a lupus nodule, and can then do its work effectually. Schiff adds the notes of several cases in which this procedure has been used, and which go to show its advantages in a striking manner. In the case of a scrofulous young girl who had suffered with well-marked nodular lupus vulgaris of the forearm, the patch being the size of an egg, the injections were employed twice to thrice weekly, while emplastrum hydrargyri was kept applied meanwhile. Within three months the disease had entirely disappeared, and up to one year subsequently showed no signs of return.

On the Composition of Jaborandi.—Dr. Albertoni (*Giornale la Saluta*) states that in Italian commerce a new preparation of pilocarpin has been introduced, under the name of *Pilocarpina Sciroposa Pura*, which, if dissolved in water and applied to the eyes of man, produces at first notable myosis, which will cease in the course of an hour, and then a mydriasis will follow, lasting from twenty-four to sixty hours. Pure pilocarpin and its salts never cause this secondary mydriasis in any dose. Longley had noticed some difference in the action of some of the preparations of the drug upon the heart, and Hardy—the first who investigated the chemical composition of jaborandi (without extracting the pilocarpin)—showed that the difference was probably due to the presence of another alkaloid. In some of the jaborandi of commerce Dr. Albertoni was able to discover only the myotic action.

Taking a certain quantity of pilocarpina sciroposa, and adding a little of $H_2Cl.$, Dr. Albertoni found that most of the substance crystallized. He separated the crystals, washed them with ether, and found that myosis was the only effect produced by them. The non-crystallizable part, which constitutes always a slight proportion of the entire mass, he also collected, and subjecting it to experiments obtained mydriasis,—its effects in general resembling those of atropia, and opposite to those of pilocarpin. He calls this new substance *anti-pilocarpin.* P. BÉTANCOURT.

TESTS FOR THE SALTS OF JABORANDI.—Roehl gives the following tests for the salts of jaborandi:

I. Phospho-molybdic acid gives with the salts of pilocarpin a *white caseous* precipitate, which detects 1 in 10,000 (watery solution), by adding HCl. 1 to 15,000.

II. Iodide of potassium (when saturated) gives a *white* precipitate in a solution of 1 to 10,000.

III. Iodide of potassium and bismuth gives a *reddish-brown precipitate* in a solution of 1 to 15,000.

Roehl attaches great importance to the *green* color which is obtained through the sulphuric acid and bichromate of potassium, and to the mode of behavior of its solutions so colored when seen by means of the spectroscope.

Cristowski, under the directions of Dragendorff, found, like Roehl, that pilocarpin could be isolated from its solutions by chloroform.

Besides the above tests we have the physiological, which is the most decisive. —Extract from *Giornale la Saluta*, 1880. P. BÉTANCOURT.

PARALYSIS AGITANS—POISONING BY HYOSCYAMIN.—M. Empis, at a recent meeting of the Société Médicale des Hôpitaux (*La France Méd.*, 1880, p. 651), reported that he had frequently given hyoscyamin in the dose of one to four milligrammes without having obtained well-marked physiological effects. In the case of a patient suffering from paralysis agitans, however, he prescribed pills of five milligrammes of this substance. The patient took his pill in the evening after dinner. Some minutes later he was seized with a sort of drunkenness, nausea, and vomiting; for some hours subsequently he felt very ill. He was not seen until the following morning. Meanwhile, finding after the vomiting was over that his hands trembled much less violently, the patient rashly took another pill. Dr. Empis, arriving a little later, found him feeling as if intoxicated; the trembling appeared to have ceased, he had a sensation as of mastic in the mouth, a little dryness of the throat, some nausea without vomiting. Violent delirium soon supervened, lasting several hours. There were four or five tetanic attacks. The patient failed to recognize his family, he saw animals about him, etc. In about three hours he began to recover. The next day he had no recollection of what had passed except the dreams of animals. M. Empis recommends that hyoscyamin should be given in one milligramme dose at first.

ACTION OF CARBOLIC ACID ON THE ANIMAL ORGANISM.—Th. Geis (*Cbl. f. Chir.*, 1880, p. 679) has attempted the experimental solution of certain as yet undetermined questions regarding the toxic action of carbolic acid, and has come to the following conclusions. He considers, with Salkowski, that increased irritability and excitability of the spinal cord are to be regarded as the causes of the convulsions. Carbolic acid paralyzes the vasomotor centres in the medulla oblongata; increase of blood-pressure does not occur with this. Conduction and dynamic force of the muscles are reduced decidedly below the normal in a frog poisoned with carbolic acid. The salivary and the perspiratory secretion are increased; the first very decidedly; whether the latter occurs from irritation of the chorda tympani, sympatheticus, or the glands, remains for further investigations to show. After death the brain shows the largest amount of phenol, then the kidneys, the blood, and the liver; the muscles show the smallest quantity. In poisoning by small and medium quantities, the cause of death, according to Geis, is paralysis of the respiratory centres. When large doses have been taken, the cause of death is stoppage of the heart and of respiration.

PHYSIOLOGICAL ACTION OF CONIUM MACULATUM.—In a communication made to the Académie des Sciences (*La France Méd.*, 1880, p. 650) MM. Bochefontaine and Tiryakian have given expression to the idea that conium maculatum contains two active principles endowed with different qualities, *conine*, *conicine*, or *cicutine*, a

paralyzant to the central nervous system, and another which acts almost like curara. A salt obtained from hemlock by M. Mourrut, the bromhydrate of conine, gives results similar to those obtained from conine. According to M. Bochefontaine, who through M. Gosselin has recently presented to the Academy a new communication on this subject, conine is absorbed by the mucous membrane of the digestive apparatus, for, having been given in a liquid form to a number of individuals, it has been found to cause general debility and the disappearance of violent pains in the stomach. Conine diminishes or abolishes the physiological properties of the nervous centres before acting like curara on the nervo-muscular connective substance. M. Bochefontaine formulates the comparative action of hemlock and curara thus: hemlock may act as curara, but it produces in addition certain physiological effects which are not noticed in animals submitted to the influence of curara.

Etiology of Chronic Ostitis and Periostitis.—Lücke (*Deutsche Zeitschr. für Chir.;* from *Cbl. f. Chir.*, 1880, p. 680) maintains that there are forms of chronic ostitis and periostitis which, although showing the same histological formation as the well-known tubercular forms, are in fact due to other causes, the prognosis in these cases being much more favorable. Most infectious diseases, acute or chronic, play a part here. In pyæmia (particularly puerperal) it is known that often, after the peculiar symptoms have passed away, secondary deposits may occur in the joints or in the epiphyseal ends of the bones. After acute infectious osteomyelitis and periostitis, the deposits are not infrequently observed to become encapsuled, latent, and later to take on a chronic form, to break out again when opportunity is given by fevers, anæmia, or trauma. The same is noticed after typhoid, variola, scarlatina, measles, diphtheria, whooping-cough, erysipelas, malaria, gonorrhœa. Syphilis is known as a cause.

Treatment of Effusions of Blood into the Cellular Tissue.—Dr. Constant (*Thèse de Paris*, 1880) says that these effusions are to be variously treated, according to the general health of the patient and the condition of the locality attacked. If not absorbed or evacuated, they may be transformed into cystic or solid tumors, which, however, do not in any case undergo change into malignant neoplasms. When large, they show little tendency to disappear spontaneously, and in such case cure may be attained by simple puncture, which is not followed by any accident, and which shortens very notably the duration of the trouble. If the skin covering the effusion becomes gangrenous, timely evacuation, before suppuration can occur, becomes all the more necessary, the danger, after the collection opens, being in direct ratio to the quantity of blood it contains. In case of suppuration, surgical interference becomes imperatively necessary, and the operative procedure is that required in a case of hot abscess. Old effusions of blood may be treated in various ways, as puncture, followed by stimulating injections, incision, or even extirpation, according to their condition, whether they are still in the liquid state or have become veritable solid tumors.

Menstruation after Hysterectomy.—Dr. Tillaux (*Bull. Gén. de Thérap.*, vol. ii., 1880, p. 231), completing the observations communicated by him to the Académie de Médecine relative to a woman operated upon last year, remarked that this individual, in whom the entire uterus except the cervix had been removed, had subsequently exhibited, as before the operation, the phenomena of menstruation. It must be stated, however, that both the ovaries had been preserved intact. In two other women, one of whom had retained the ovaries after hysterectomy and the other had suffered their removal, the menses had in the first case appeared and were kept up, while in the latter case they disappeared and did not return.

Double Urethra.—J. Dollinger (*Pester Med.-Chir. Presse;* from *Cbl. f. Chir.*, 1880, p. 688) reports a case of a man of 28 who had urinated through two openings from birth. The penis and glans were well developed. On the dorsal side of the glans was a deep gutter, which ran into the cavernous portion of the penis. Three and a half centimetres behind the point of the glans this gutter ended in an opening the size of a No. 12 catheter, and three and a half centimetres in length, which terminated in the normal urethra, the external opening of the latter lying farther up, so that a sort of epispadias existed. An operation resulted in restoration of the normal relationship of parts.

EDITORIAL.

GYNÆCOLOGY, VIEWED BY A GENERAL PRACTITIONER.

ALTHOUGH gynæcology is acknowledged as a true specialty, it must be admitted that it occupies towards general practice a very different position from that of ophthalmology. It is allied so closely to obstetrics, which of necessity, till the very constitution of things is altered, must form a prominent part of the family physician's work, that it is hard to draw the line and say how far the general practitioner should intrude himself upon the gynæcologist's field, or, more properly, how far the gynæcologist should be allowed to usurp the field already occupied from time immemorial by the family practitioner. At what shall the latter stop? Certainly he must know enough to perceive the necessity for recommending his cases to the specialist; and between the knowledge requisite to diagnose a uterine displacement and that required to rectify it by a properly-adjusted pessary is but a small step; and in local congestions, erosion of the cervix, menorrhagia, leucorrhœa, the use of the curette, and applications to the cervical canal, and even to the fundus uteri —at what point is he to pause?

Perhaps the greater operations—the removal of tumors, polypi, fibroids, and ovarian cysts, the cure of fistulæ and lacerations—would about cover the field of the gynæcologist and indicate the point where the family doctor could leave his patient, having seen her safely there, in the hands of the great man. But the specialist is not by any means disposed to limit his practice in this manner. He claims the right to be considered an expert in obstetrics on occasion, and considers himself as the only proper custodian of all cases of uterine disease; nor do his large fees leave the usual attendant any chance, for where the circumstances of the patient are too limited to admit of such payment he offers the facilities of his free clinic or dispensary, with the ægis of his great name.

In rural practice, of course, the specialist is not so accessible, but it is a mean city to-day which cannot boast at least one skilful gynæcologist, and the already narrowed field of practice on which, it seems, we general practitioners have been squatting since the time of Hippocrates is being rapidly claimed and enclosed by these lords of the soil, till at last it may happen that the whole class of general practitioners will be evicted to make room for still more enterprising claimants, who will divide and subdivide till, by retributive justice, the holdings will become too small to support their occupants. Then the specialist who removes ovarian tumors will sullenly glare at him of the uterine fibroids, and the wielder of the tenaculum come to blows with him of the curette.

But to avert that dreadful day it behooves each practitioner to fit himself as much as possible for advanced gynæcological work, that the patient, if she by evil chance break forth from his hand uncured, may at least have paid him tithe before she goes. To acquire this knowledge requires both courage and industry. Only those especially favored by circumstances and location can enter again upon a student's career, and books must therefore afford them the information which the graduate of to-day has almost unconsciously imbibed.

The books that are to supply the stone for these defensive fortifications are not far to seek: they are furnished by the enemy himself. They should be, not the work of a novice, who teaches himself as he writes, nor the product of the book-maker, who

sees in publication a rapid step to reputation, nor even the labored compilation or the elaborate treatise of the scholar, but books which are the mirror of the daily work, the daily and hourly experience and expedients, of a practical master. The new edition, so fresh that it yet reeks with the odor of the printing-room and the bindery, of the treatise by Prof. Thomas, of New York, might well furnish the material for the first line of intrenchments, whilst to the inner citadel might be assigned the "Lessons in Gynæcology," by our fellow-townsman, Dr. Goodell.

Lay deep, then, O brother-practitioners, the foundations of that knowledge which shall be our sure defence against that spectre, whose name is Gynæcology, which now confronts us in the doorways of our choicest patients,—

"A formidable shape:
The one seemed woman to the waist, and fair,
But ended foul in many a scaly fold,
Voluminous and vast, a serpent armed
With mortal sting."

We are always pleased to note honors paid to naturalized as well as native citizens of Philadelphia. The late Benjamin Cartwright, of Newark, New Jersey, besides leaving a sum of money to the Pathological Laboratory Fund of the Alumni Association of the College of Physicians and Surgeons in New York, established a course of lectures to be given yearly, and Dr. Roberts Bartholow has been selected to deliver the first course.

CORRESPONDENCE.

BOSTON LETTER.

Mr. EDITOR,—Do we, in our rich possession of the advantages of medical centres,—the hospital, the clinic, the well-stocked library, the ever-freshly-laden tables of the medical reading-room, and, above all, the abundance of opportunity, when we are cornered, to consult other and wiser men than ourselves,—do we realize the severity of the deprivation of all these comforts, luxuries, and aids which it is the lot of the country practitioner to bear? How enviable, in these respects, must he consider our privileges! If he can afford it, he has his medical journal, and occasionally allows himself the luxury of a new book. But in the monotony of his daily round, his long drives over hill and through woods in dark night and stormy day, what has he by way of medical refreshment and professional recreation? Nothing but his little shelf of books, his love of medical work, his good courage, self-confidence, and self-dependence. A dreary outlook, one would think; a most juiceless life. But yet there must be a compensation in the thought of duty faithfully performed, of unselfish and untiring devotion to the sick in the face of small fee or none at all.

They are brave, true-hearted men, these isolated, hard-working country doctors. And their mere isolation and lack of all brotherly intercourse with fellow-practitioners give them a fibre, a mental muscle, a fertility of expedient, a coolness in danger, a power of self-knowledge and self-reliance, which many a city physician never has the opportunity for developing. I am not sure that the life of the country doctor would not prove a wholesome tonic to us of the cities. Every need of ours can be supplied almost on the instant; aid and instruments of every sort lie ready to our hand or within call. But the doctor of the hill, wood, and farm must depend upon himself and his few instruments. His aids are the uncultured people about him. What he does in a time of danger must be done at once or not at all. Waiting brings *him* no help. And thus he learns to meet difficulty with readiness. Thus is he forced to create his own resources. Thus he rounds out his every faculty, moral, intellectual, and mechanical. If you have ever talked with one of these prompt, cool, unflinching men, you doubtless have been surprised by his common sense, his faculty of observation, his intuitive power in diagnosis. He is not a theorist, not a book-man. He follows modes of treatment which are credited to great names in the books, but he may never have heard or read of them. He is a sort of medical Robinson Crusoe, who hews out his own appliances, overcomes obstacles and dangers with means of his own improvising. Happy is he if he have the help even of an untutored Friday. All honor and respect to these noble men, say I. Without praise, without fame, perhaps almost unknown, save in the little circle of their patients, they toil on without rest and with little reward until they die. One joy they do possess; they are devotedly beloved and honored by those whom they serve.

It occasionally occurs, however, that the ability of a country physician is of a quality and accomplishes results which cannot be kept under a bushel. He does a surgical operation of infinite difficulty under conditions which would absolutely discourage a man of a lower degree of self-reliance, or he brings about a recovery from the very jaws

of death by an instantaneous appliance of a remedy the details of which would deter a city physician from making use of it unless he had every complication of modern improvement to aid him, while his country *confrère* will satisfy himself perforce with the veriest of all primitive materials, and be successful at that.

Let me tell you of such a man, one who has been famous, who became famous in spite of his modesty, and whose memory should be revivified, for it is in danger of being forgotten.

Dr. Amos Twitchell, of New Hampshire, born in Dublin, of that State, in 1781, became an office-student under Dr. Nathan Smith in 1803, after graduating at Dartmouth. He began to practise in 1805. At the expiration of two years he wrote, "I find I am doing poorly; some of my patients have run away, others are unable to pay, and not any of them *do* pay." Experience of this nature depressed him. He moved to another village, with the purpose of devoting himself to surgery. He had enjoyed a somewhat large experience in dissection under Dr. Smith, and surgery was his natural specialty. Having already been two years in country practice, his native courage, quickness of decision, and readiness in resource had rapidly matured.

It was just at this time that he performed an operation which invested him with a fame of life-long endurance. This was nothing less than *tying the common carotid*, which, while common enough now, at that time, to Dr. Twitchell at least, was an unknown procedure. Hebenstreit, a German surgeon, in a translation of Benjamin Bell's Surgery, mentions a case in which the carotid was wounded during the extirpation of a scirrhous tumor. The surgeon at once tied the trunk of the vessel, and the patient recovered. This, according to Cooper's Surgical Dictionary, is probably the first authentic instance of ligature of the common carotid. In 1798 Abernethy was forced to tie the carotid in a case similar to Twitchell's, but the results were such as would only confirm the general belief of that day, that the operation was neither allowable nor safe. In 1803 Mr. Fleming, an English naval surgeon, tied the vessel in a case of attempted suicide, and saved his man; but the case was not published until 1817. In the same year (1803), according to Dr. Bowditch (Twitchell's biographer), Dr. Cogswell, of Connecticut, tied the carotid during an operation for the removal of a cervical tumor; the patient died in three weeks, and the details were not published for years afterwards. Velpeau states that in 1804 Dubois intended to do the operation, but his patient died before he had begun. In 1805 Sir Astley Cooper operated for aneurism of the carotid, and tied the trunk; the patient died. And it was not until 1808 that Cooper "proved the feasibility of tying this vessel with perfect safety to life." He did not publish his case until 1809.

It seems, then, that when Dr. Twitchell did the operation, in October, 1807, not only was surgical opinion generally opposed to it, but that no previous operation, with the exception of Abernethy's, could have been known to Dr. Twitchell in a published form; and Abernethy's case was not encouraging, for his patient's brain became affected, and he died. Moreover, Dr. Twitchell positively asserted that he was totally ignorant of the fact that the vessel had previously been tied by any one, although from his own experiments on animals he had been led to *surmise* that it could be closed in man. So much do we learn from his biographer, who adds, "Why, then, should he not stand in the same rank with Abernethy and Fleming, so far, at least, as one operation shows the calibre of a man's mind?" But I suspect—a point of comparison not touched by Dr. Bowditch—that both Abernethy and Fleming had every convenience and a staff of assistants besides, while Twitchell was almost absolutely unaided at a moment of terrible stress and danger.

Moreover, when Abernethy tied the carotid he was thirty-four years of age, and had been practising surgery at least twelve years. The age of Mr. Fleming does not appear; but, since he was an English naval surgeon, and performed his operation in 1803, it is more than probable that his age was mature, and he undoubtedly had seen a vast amount of surgery during the peppery times in which he lived. One other point. Both Abernethy and Fleming, especially the former, naturally had seen much surgical practice in hospitals. Now look at the other side of the shield:

When Dr. Twitchell tied the common carotid he was only *twenty-six* years of age, had been in practice but *two* years, and of course, even while educating himself in medicine, having *always* lived in the country, he had seen but a very limited amount of surgical practice. In any case, surgical operations in this country, between the years 1800 and 1804, were nowhere very numerous.

For the other details of the case let me briefly quote from Dr. Twitchell's notes: "During a mock-fight a cavalry soldier received a wound, from a pistol discharged near him, on the right side of the neck and face." The injury was very serious. On the tenth day he writes, "I applied the usual dressings, left the room, and was about leaving the house, when some one cried out that the patient was bleeding. I hastened back, and found him deluged with blood. The dressings were immediately removed, and the blood jetted forcibly in a large stream to the distance of three or four feet. With the thumb of my left hand I instantly compressed the artery against the base of the skull, and thus effectually controlled the hemorrhage. The patient had fainted, and fifteen or twenty

minutes elapsed before he was so much revived that I dared make any attempt to secure the artery. Then, still keeping my thumb firmly pressed on the orifice, I proceeded to clear the wound from blood; and, having done this, I made an incision with a scalpel downward along the course of the artery to a point more than an inch below the location where the external branch was given off, and which, as mentioned, had been destroyed at the time of the injury. *Having but one hand at liberty, I depended upon the mother of the patient to separate the sides of the wound* [italics mine], which she did, partly with a hook and occasionally with her fingers. At length, partly by careful dissection and partly by using my fingers and the handle of the scalpel, I succeeded in separating the artery from its attachments, and, passing my finger under it, I raised it sufficiently for my assistant to pass a ligature round it. She tied it with a surgeon's knot, as I directed, at about half an inch below the bifurcation." And thus, with *no other assistant than an aged woman*, and she the mother of the patient, and with *only one hand at liberty*, did this brave young man perform the hazardous operation the details of which he gives with such striking modesty!

But the call upon his ingenuity and coolness was not yet ended. "I removed my thumb," he says, "and sponged away the blood, not doubting that the hemorrhage was effectually controlled; but, to my surprise and disappointment, the blood immediately began to ooze from the rupture in the artery" (collateral circulation), "and in less than ten minutes it flowed with a pulsating jet. I again compressed it with my thumb, and began to despair of saving my patient. What further could I do? It was impossible to apply a ligature above the orifice; compression, then, was the only alternative." After considering the pros and cons of digital compression, he finally raised his thumb and applied a bit of dry sponge over the orifice in the artery, upon this a second and larger piece, thus adding piece after piece, each being a little larger than its predecessor, until he had filled the wound with a firm cone of sponge, which pressed upward and backward against the base of the skull, the broad portion of the cone projecting two or three inches externally. This was fixed by a roller-bandage, and the patient was then put to bed. His escape from death was a narrow one, but the wonderful and ready coolness and ingenuity of Dr. Twitchell had saved him, for he made a good recovery.

Dr. Twitchell, with characteristic modesty, subsequently wrote, "This case seemed to me at the time highly important and valuable, since it established facts which, so far as my knowledge extended, had not till then been known. The question of the practicability of the safe application of the ligature to the common carotid artery was, in my opinion, now solved." But, in spite of this opinion, Dr. Twitchell would not allow the publication of the case until thirty years had elapsed, and then only upon urgent solicitation, because *the operation was forced upon him, and not undertaken voluntarily.*

Is there another case on record of ligation of the common carotid by a young surgeon of only two years' practice, *the operation being performed with one hand and an ordinary scalpel, the only assistance being rendered by an old woman, and she the mother of the patient?*

In 1840 Dr. Twitchell made what was then considered a very remarkable diagnosis. He asserted that a patient who had been under the care of the most eminent of the faculty had pus in the tibia, and, upon trephining the bone, found one and one-half ounces of pus. Sir Benjamin Brodie, in 1832, had published a paper giving details of two similar cases in which he had trephined; but Twitchell thought this operation was his own, for he had never heard of or seen Brodie's paper. He was offered professorships in various New England colleges, but declined them all. He was invited to move to Boston, but preferred to remain in Keene, to which place he finally moved, and where he died in 1850, beloved by all who knew him and held in high esteem by his contemporaries throughout the country.

Surely the memory of such a man—a thorough physician and a brilliant surgeon—should be kept fresh. I am glad to say that a fine likeness of Dr. Twitchell occupies a prominent place in the rooms of the Boston Medical Library Association.

A brief allusion may be made to a second country physician and surgeon now living in Keene, New Hampshire, and considered the leading surgeon of his State. I refer to Dr. George B. Twitchell, nephew of him whose ability I have endeavored to show, and who seems to have inherited the self-reliance, ready skill, and courage in emergency so characteristic of his uncle. A single instance of his power will suffice.

In August, 1879, this gentleman was called, in consultation, to a case of progressive anæmia. The patient was a woman aged 45, who had fallen through a broken floor. This was followed by severe cramps in the stomach and bowels. Constipation and vomiting supervened, the latter being so violent and incessant that it continued almost without exception for five weeks. Every means of nourishing the patient had been tried in vain. She became so reduced and so feeble that the radial pulse disappeared and the respirations numbered only five to the minute. When Dr. Twitchell was called, he said that in transfusion lay the only hope of saving the patient. With Dr. S. A. Mason, of New York, who temporarily had charge of the case, the possibility of procuring instruments from New

York was discussed; but it was seen that the emergency was too serious: death would ensue before the instruments could be obtained. It was then decided to use such aids as were at hand. Dr. Twitchell went for an old canula once belonging to his uncle, and for a fountain-syringe. With these primitive aids and a scalpel the operation was performed. Blood was drawn, to the amount of six or eight ounces, from the arm of the patient's son. It was caught in a bowl, the fibrin whipped out with a fork, the blood being kept at the proper temperature by setting the bowl containing it in a dish filled with warm water. Finally it was filtered from coagula by means of a handkerchief. Everything being ready, Dr. Twitchell began the operation, but was at once disheartened by what threatened to be a fatal syncope. The patient, however, was revived, and Dr. Twitchell proceeded. He had only the old imperfect canula, which lacked a trocar, and, moreover, the vein of the patient's arm was so collapsed that a dissection was necessary. Following this, the vein was lifted and incised, and the canula, having been attached to the syringe by slipping the hose over its free end, was introduced into the bloodless vein. The syringe, of course, before the blood was emptied into it, had previously been warmed and cleansed by means of hot water. So soon as the blood began to flow, the patient, who could not speak aloud, whispered, "I feel that blood." From an imperfection in the canula, some of the blood was lost. Six ounces more were therefore taken from the son's arm, and, after having been put through the defibrinating process already described, were injected without loss. At the close of the operation the patient's cheeks showed a slight flush. A little milk was given, and, for the first time in weeks, was not rejected by the stomach. Nourishment was carefully administered in increasing amounts, and the result was a complete recovery of health.

This operation, it seems to me, in its way, was as daring, and showed as much self-reliance and readiness of resource, as that performed by the elder Twitchell. In this case, too, the operation was determined beforehand, when the great obstacles had opportunity to discourage the operator, while the other was forced upon the surgeon. Are there many surgeons who would undertake transfusion with a scalpel, a fountain-syringe, and an old-fashioned canula? In view of the complicated and perfect apparatus now used in this operation, it is probable that if the average surgeon had the old canula he would not think of the fountain-syringe, and if he had both would not dream of attempting transfusion with them alone.

This operation showed a heroism which should win for Dr. Twitchell the highest meed of praise. The case was reported in the *New York Medical Record* by Dr. Mason, but in a very simple manner, the bare facts alone being given. I have seen no allusion to it, and if Dr. Mason had not communicated it to the medical world it is probable that Dr. Twitchell would never have done so, for, like his uncle, he is a man who works for results and not for praise. A simple, genial, brave gentleman. Would there were more physicians like him in the cities as well as in the country!

Boston, November 2, 1880.

REVIEWS AND BOOK NOTICES.

A Practical Treatise on Fractures and Dislocations. By Frank Hastings Hamilton, A.M., M.D., LL.D., Surgeon to Bellevue Hospital, etc. Sixth American Edition, revised and improved. Illustrated by three hundred and fifty-two wood-cuts. 8vo, pp. 909. Philadelphia, Henry C. Lea's Son & Co., 1880.

This excellent and exhaustive treatise, which is so thoroughly appreciated both at home and abroad as to demand no commendation at our hands, has been enlarged by upwards of one hundred pages, and materially improved by the addition of a chapter on general prognosis, and by a revised chapter on fractures of the patella, the latter of which is a *résumé* of a separate brochure on that subject.

In the chapter on general prognosis Dr. Hamilton earnestly combats the extraordinary and pernicious doctrine of Dr. Sayre in regard to the union of fractures of the long bones without shortening, and shows that his statements are based upon erroneous observations of, as a rule, imperfectly-recorded cases in Bellevue Hospital. Indeed, in view of the unequal length of the bones of both extremities,—a fact which has been fully established by Cox, Hunt, Wight, and Morton,—the measurement of limbs is almost valueless. At page 437 Dr. Sayre is placed in a most unpleasant light by the positive denial by the author that he measured the limbs which Dr. Sayre asserted were cured without shortening.

In the chapter on fractures of the patella we are surprised to find that, among the numerous appliances which are described and depicted for their treatment, there is no notice of the apparatus of Agnew, nor of the modifications of Malgaigne's hooks made by Dr. Levis and Dr. Morton, which have been so successfully employed in this city, and through the use of which bony union has certainly been obtained. Among the earlier papers on the subject, with which Dr. Hamilton should have been familiar, reference may be made to one, with an illustration, contributed by Dr. Levis to the *Medical Times*, May 26, 1877, and to another from the pen of Dr. Morton,

which appeared in the *Medical News and Library* for December, 1879. Our own opinion—and we are sustained in it by many of the best surgeons of this city—is that ordinary appliances interfere with the nutrition of the patella to such a degree that fibrous union alone is to be looked for. With the view to obtain bony union nothing could be better than the improved hooks to which we have alluded.

Among other omissions—and they are inexcusable on the part of an author who has devoted the best years of his life to the preparation and the revision of several editions of a practical treatise—the following may be noted: the failure to give credit or even allude to the procedure of the elder Pancoast for securing the fragments of ununited bones by means of a metallic pin or screw,—an operation which he first performed in 1857, and which is fully described in Gross's Surgery; no allusion to Professor Bigelow's sub-periosteal resection and wiring the ends of the bone,—a practice which was attended with ten cures out of eleven cases; no mention of Bryant's test-line in the diagnosis of fracture or shortening of the neck of the femur, or of his treatment of fracture of the thigh in children by vertical extension; no reference to the splints of Levis, Gordon, and Coover for fracture of the lower end of the radius; nor any mention of Allis's diagnostic sign of fracture of the neck of the femur, namely, a relaxed condition of the fascia lata between the crest of the ilium and the great trochanter, nor of that gentleman's investigations in regard to the deformity from fractures involving or approximating the elbow-joint.

Among other shortcomings are an inadequate description of the very useful and readily-applied Bavarian bandage, and the illustration at page 479 showing the application of adhesive plaster for making extension in fractures of the femur. Instead of being carried above the knee, the strips terminate below that articulation. Dislocations of the hyoid bone are not described.

In referring, in his preface, to certain omissions in the treatises of Gurlt and Malgaigne, Dr. Hamilton remarks that they are "defects which might have been easily remedied in later editions if the authors had seen fit to do so." For this reason he can scarcely find fault with the reviewer who directs attention to his own omissions, particularly when such criticism is meant to make him more careful in the preparation of future editions.

On Slight Ailments, their Nature and Treatment. By Lionel S. Beale, M.D., F.R.S., etc. Philadelphia, Presley Blakiston, 1880.

"The maintenance of each individual organism in a good state of health, and careful attention on the part of the practitioner to slight ailments, are . . . of far greater importance practically than the hunting and extermination of various species of hypothetical pathological bacteria, even though it were actually possible to catch and exterminate legions." In such forcible language does the author express his sense of the gravity of his subject.

From beginning to end there is little of the new and precise therapeutics of the day, while the now despised empiricism, or experience with ignorance, whether individual or garnered from past centuries, is extolled on almost every page. Wherever with his microscope, however, the writer can light up and examine, *con amore*, some dark corner, or where he pauses to discourse learnedly upon a flea-bite, the truly scientific person can find much interesting matter.

The author's therapeutics for slight ailments are neither new nor very varied. Old-fashioned purgatives, emetics, acids, and antacids find most favor in his eyes, and, while professing to instruct in the old, fast-fading formulæ, we miss very many remedies sanctioned by experience and antiquity. Almost instinctively in such a work one turns to "Headache" and "Indigestion," as tests of the author's practical value. The ideal treatise on indigestion has yet to be written; we do not find it here, though there is much that is instructive and entertaining. Headache, which is synonymous in his view with biliousness, he considers as a derangement of the digestive organs. If there were perfect digestion and excretion, there would be permanent cure. In impending cases his favorite, mercurial with colocynth, followed by a saline, is recommended, but in its distressing actuality the first remedy given is "to persuade the patient to think as little about it as possible," and go about his business, abstaining from food absolutely. Where the victim refuses to treat the matter so lightly, he must keep warm, soak the feet, sinapism the nape of the neck and pit of the stomach, take lemonade if he crave acids, and drink strong tea, even to five cups. The author is evidently benefited by strong tea in his own attacks. It is refreshing to read (p. 222), "I can assure you that the very confident, unqualified condemnation of mercurials that has lately been so fashionable rests on no foundation of fact. . . . I could give examples of life being prolonged to more than eighty-four, although one or two grains of blue-pill had been taken every fourth or fifth day for forty years." Strong medicine, without blood-letting, however, is recommended freely; the forgotten virtues of black-draught and nitre-balls are extolled. "In these days," he says, "not only do we neglect to use many of the old prescriptions, but we no longer suggest new ones." Now, while the author has not done the former, he has left the latter almost undone, since we have not met, in a careful reading, a single new, original combination. E. W. W.

SOELBERG WELLS ON THE DISEASES OF THE EYE. Third American Edition, with Copious Additions by CHARLES STEADMAN BULL, A.M., M.D., Surgeon and Pathologist to the New York Eye and Ear Infirmary, Lecturer on Ophthalmology in the Bellevue Hospital Medical College. Philadelphia, Henry C. Lea's Son & Co., 1880.

Since the issue of the first edition of this most estimable work in 1869, it has held its place as one of the leading text-books on ophthalmology in the English language, if not really the leading one. It came out just at the right time. There was nothing for us English people but Mackenzie, a splendid work in itself, but somewhat too antiquated for the times.

Dr. J. Soelberg Wells, F.R.C.S., was an early and attentive student of the leading Continental teachers of ophthalmology, especially of the great, lamented Von Graefe. In his work he lays great stress upon the observations and teachings of that renowned ophthalmologist, and was the first to present his ideas fully to those reading only our language.

Dr. Wells's long connection with the Royal London Ophthalmic Hospital, as well as his position as Professor of Ophthalmology in King's College, London, gave him abundant material for personal observation to bring into his work.

The first edition was soon absorbed, so that it was necessary to issue a second and then a third, which having been sold, a fourth was in preparation, but, his health becoming shattered, he left England for Cannes, in the south of France, hoping that the change to a mild climate would be of benefit to him; but, it being otherwise ordained, he died there in December, 1879, thus preventing the issuing of the fourth edition.

The book being entirely out of print, and the demand for it still continuing, Dr. Bull has taken in hand the editing of an American issue of the last edition, with the necessary additions to bring it up to the present day.

Dr. Bull has done his work quite well and judiciously, by introducing notes embracing almost all of the advances in ophthalmology since the appearance of the last issue. He has also more fully illustrated it than the last English edition.

The typographical errors are not numerous. One, however, it would be well to notice on account of its misleading the student, and that is on page 236, where an effusion of blood in the anterior chamber is called "hyperæmia" instead of "hypæmia," or, as the Continental writers call it, "hyphæmia."

It is true that we have very good translations of foreign works on ophthalmology, some of which are perhaps fuller and more complete in many ways, but none are handier, clearer, and more explicit than this of Wells.

As a text-book it is excellent; but it should be understood by the student and general practitioner that the study of this book alone does not make a perfect ophthalmologist. There is very much more theoretically and practically to be learned before one is thoroughly capable to diagnose and treat any and every form of disease and affection of the eye, and make all operations on that organ that may come before him. It is intended to give such an insight into that branch of medicine and surgery as shall lead one to further and deeper study, and to prevent the many mishaps that have occurred and may occur in a general practice from want of knowledge of the seriousness of the diseases and affections of the eye, and the necessity of calling in or sending early to the specialist. K.

FRACTURE OF THE PATELLA. A STUDY OF ONE HUNDRED AND TWENTY-SEVEN CASES. By FRANK H. HAMILTON, A.M., M.D., Surgeon to Bellevue Hospital, etc. 8vo, pp. 106. New York, Chas. L. Bermingham & Co.

A careful examination of this book has failed to convince the reviewer of its being a complete monograph on the subject of fracture of the patella. It certainly is a *mono*-graph, since it treats of only one side of the subject. It is not, however, the elaborate consideration of the injury in question which it was hoped Dr. Hamilton would give us. Much has been done of late in Europe and America to perfect, or at least to endeavor to perfect, the methods of treating this usually unsatisfactorily treated fracture; and yet, we may justly say, nothing of importance has been said of these experimental inquiries. The treatments by hooks, by wiring, and by carbolized sutures, which have been so frequently mentioned in the German, English, and American journals, receive no notice,—either because the author has not taken time to bring his work up to the present state of knowledge, or because he does not believe in novelties or revived methods of treatment. In either case the volume is diminished in value, since the profession always looks in monographs for the latest views and most judicious criticism pertaining to the subject discussed. Very nearly three-quarters of the book (73 pages) are occupied by unimportant details of cases,—details which are of little value when accurately given, but absolutely worthless when compiled from hospital records inaccurately kept. The last two chapters, consisting of an analysis of the cases and of some general remarks made on the subject at the clinic of Bellevue Hospital, are really the only portions of the volume that are likely to be read.

Muscular contraction is considered the chief factor in producing transverse fracture of the patella, and undoubtedly the author is correct in his belief, since the experience and observation of all surgeons support this view. The injury is far more frequent in man than in

woman, and in the middle period of life than in childhood or old age, which facts also seem to point to its causation by muscular contraction. The method of treatment preferred by Prof. Hamilton is to elevate the limb, and apply a moulded posterior splint of leather from the middle of the thigh to the ankle. Bandages are then applied from the ankle upwards and from the hip downwards, while the fragments are held together, as well as can be done, by circular turns of the bandage just above and below the bone.

The typographical appearance is good, and it is unfortunate that the volume has not been more carefully compiled and the subject more elaborately discussed, as it would then take a high place in surgical literature, which possesses little in a permanent form on the subject of fracture of the patella. J. B. R.

A Manual of Minor Surgery and Bandaging. By Christopher Heath, F.R.C.S., Surgeon to University College Hospital, and Holme Professor of Clinical Surgery in University College, London, etc. Sixth Edition, revised and enlarged. Philadelphia, Lindsay & Blakiston, 1880.

The rapidity with which successive editions of this manual have been called for by the profession, both in England and America, is a worthy tribute to the deserved popularity of the distinguished author and the excellence of his work. In the introductory chapter, as in previous editions, the general duties and the conduct of hospital-residents are clearly set forth, a close adherence to which would make the services of resident physicians more profitable to themselves and satisfactory to their chiefs and the managing boards of hospitals. The general and local treatment of hemorrhage and the various methods of resuscitating patients in vogue at the present time are considered with a fulness of detail that the importance of these subjects warrants. A full description of the antiseptic system as practised by its advocates in the treatment of wounds is contained in this edition: the author, however, expresses no opinion in regard to the relative merits of Listerism. Considerable space is likewise devoted to the present popular plan of treating curvatures of the spine by means of plaster-of-Paris jackets, and in connection with this subject our distinguished countryman Professor Sayre receives the credit due him for this valuable contribution to surgical therapeutics. Chapter X. contains a brief account of the splints recently devised by H. O. Thomas, of Liverpool, for the treatment of diseases of the hip- and knee-joints; there is no notice, however, of the important modifications of these splints that have been made at the suggestion of Professor Agnew. The work is illustrated by one hundred and fifteen wood-cuts, the majority of which have appeared in former editions. C. T. H.

Diseases of the Pharynx, Larynx, and Trachea. By Morell Mackenzie, M.D. 8vo, pp. 440. New York, Wm. Wood & Co., 1880.

This book is a reprint of the first volume of Dr. Mackenzie's "Diseases of the Throat and Nose." No mention being made of the fact that it is an incomplete work, the reader might be deceived into accepting it as a distinct production from the foregoing.

The illustrations are rude copies of the originals, with names of New York cutlers engraved upon them, or, when not so marked, with the name of the English cutler omitted. The scale upon which the drawings are made is not infrequently dropped, and other liberties are taken with the originals. We say the wood-cuts are rude. We can go farther: many of them are caricatures. They are worse than useless, since they mislead. We regret that Dr. Mackenzie should have permitted this mutilated volume to appear. In the event of his not having sanctioned the enterprise, the action of the publishers, in our judgment, is scandalous, and should be rebuked by the profession.

Minor Gynæcological Operations and Appliances for the Use of Students. By J. Halliday Croom, M.B., M.R.C.P.E., etc. Edinburgh, E. and S. Livingstone, 1879.

Both of these manuals for students will be found very useful, and, from their small size and clear print, would not be useless to practitioners in general as handy books for the pocket, to be perused in the spare minutes. The manual of Dr. Croom is profusely illustrated, and the specula, pessaries, sounds, and sponge-tents are almost life-like. Page 29, however, presents a picture over which the reader may well pause in astonishment, for in it is seen a woman, forlorn, slightly clad, lying on the sands of some desolate shore, and clinging to a rock with both arms. At her side the tide can be seen rising. The text, however, reveals the fact that she is only in the ordinary gynæcological position, lying on a mattress and grasping a pillow. The water is the side of the mattress, while on the opposite page are portrayed a Cusco and a Sims speculum. The romance disappears; the prosaic reasserts itself. E. W. W.

A Treatise on Foreign Bodies in Surgical Practice. By Alfred Poulet, M.D., Assistant-Surgeon-Major, etc. 2 vols. 8vo, pp. 271 and 321. New York, William Wood & Co., 1880.

These volumes constitute a valuable addition to surgical literature, but the cheap manner of their getting up,—which, we presume, calls for poor paper, trying type, and execrable wood-cuts,—as well as the absence of running heads, save the title of the work, so greatly detracts from its value that we advise our readers to purchase the original.

GLEANINGS FROM EXCHANGES.

TREATMENT OF SPRAINS BY MASSAGE.—Dr. Bérenger-Féraud, an old army surgeon, gives an account of four hundred sprains which he treated successfully with massage. He speaks as follows:

I think it necessary to tell in detail how, in my opinion, a person ought to proceed when he undertakes to treat a sprain by massage, for it is by indicating very clearly the manner of proceeding which has succeeded, that those who are beginners are put under the best conditions to obtain a success at the first essay which they may make of the method. Let us suppose that we have a sprain of the foot. After we have arrived beside the wounded,—and note in beginning that the nearer the massage is to the moment of the accident the shorter is the treatment,—we make him sit upon a chair if he is up; we seat ourselves in front of him and make him put his injured foot upon our knees. If, on the contrary, the subject is lying down, it suffices to uncover him, and if need be to unbandage him in order to make a diagnosis. This diagnosis being established,—that is to say, when we have found out that we have to do with a sprain, slight, medium, intense, or complicated,—we proceed to the manipulations. We begin by making on the dorsal face of the foot, going from the root of the toes to the leg, following the direction of the extensor tendons, passes as light as possible with the pulp of the four last fingers, anointed from time to time with some fat body,—olive oil, for example. These frictions, which ought always to be directed from the extremity towards the root of the limb, and never in a contrary direction, are extremely light; they begin quite far above the painful part, and are prolonged as far below. They ought not to be painful; and in the cases in which, in spite of their extreme slightness, the subject finds them too painful, it will be necessary to begin at some other region, leaving the dorsum of the foot to return to it when the sensibility has been a little blunted by the massage.

Little by little the pressure is augmented, and at first the pulp of the four last fingers of both hands, then that of the two thumbs, intervene, according as the contact is less painful for the patient. A few minutes after beginning, in general, one may press very notably on a place which at first could not support the slightest friction without suffering. Soon after it is a veritable friction, quite strong, that we may practise, taking care to have recourse to the fat body to protect the skin of the patient, which would not be slow to become excoriated if it were kneaded dry, and the pulp of the fingers feels a sort of peritendinous œdema which one makes mount upwards little by little above the ankle, as far as the fleshy portion of the extensors of the toes and of the anterior tibial.

According as the contacts are less painful, we cause slight movements to be executed upon the articulations in the neighborhood of those which are injured, and one arrives thus little by little at those in which the sprain has spent most directly its effects. These movements are very gradual; imperceptible at first, they go on little by little increasing, until at the end of the *séance*, which it is necessary to prolong willingly, pain being always very carefully avoided, we cause the part to execute all its physiological movements in their greatest amplitude.

At certain moments we may feel under our fingers substances like small nodosities, more or less voluminous, large as a lentil,—nodosities at first fixed, afterwards movable, of which the patient is conscious, and which give an impression of pain when pressed a little forcibly. It is necessary to pass the fingers with persistence over them, taking care to do so lightly enough not to make the patient suffer; and, moreover, they must be mobilized little by little,—at first chasing them very gently, afterwards as far as the fleshy portions of the extensor muscles of the toe and the tibialis anterior.

At the end of a time which varies from one to five minutes, friction may be applied with greater and greater force, and soon strong pressure provokes no sensible pain. This is the moment to leave this portion of the foot to knead either the more external part or the internal part, by passing then along the border of the foot as far as the malleolus, which is turned in such a manner as to follow either the tract of the peroneal tendons or that of the muscles of the posterior tibial region. We act upon each of these regions, as I have said previously, going from the lightest rubbing to vigorous friction, taking as a guide the impressions made upon the patient, and taking great care not to hurtle against an osseous eminence.

The *séance* ought to continue until all feelings of distress and pain have disappeared. When the operation is once terminated, a retentive apparatus is applied.—*Canadian Journal of Medical Science;* from *L'Union Médical du Canada.*

ATROPIN AS A PREVENTIVE TO THE CARDIO-INHIBITORY EFFECTS OF CHLOROFORM.—Mr. E. A. Schäfer, writing to the *British Medical Journal* (vol. ii., 1880, p. 620), says, speaking of a death from chloroform, during an operation, when injections of atropin had been used, that it is well known that atropin paralyzes the cardiac inhibitory apparatus. Since it is probable that death in these and similar cases results from a stimulation of this apparatus, either directly by the drug, or, it may be, in some instances, in a reflex manner, by the stimulation of abnormally excitable afferent nerves during the actual performance of the operation, there undoubtedly seems good reason for the employ-

ment of atropin. But, clearly, it should always be given immediately before the administration of chloroform, *as a preventive;* for if the heart's action has completely stopped, the circulation having once ceased, of course no cure is possible; and even if the inhibitory action has only much slowed and weakened the heart, without having actually arrested it, the absorption of the atropin would probably be too long delayed to be of any avail.

CASE OF MALFORMATION OF THE HEART.—Dr. Thomas B. Peacock reports (*Lancet*, vol. i., 1880, p. 530) a case of great constriction or stenosis of the orifice of the pulmonary artery; aorta arising from both ventricles; defects in the fold of the foramen ovale; the ductus arteriosus closed. The patient was a child one year and seven months of age, and the signs of malformation of the heart were very marked. The lips, hands, and feet were very livid; the ends of the fingers and toes were clubbed, and the nails incurvated. The cyanosis was probably present from birth, but it first attracted decided attention when the child was nine days old. It had gradually grown more marked from that time. The jugular veins were distended, and there was a systolic murmur heard in the region of the heart. The child was very easily chilled. Its digestion was difficult, and when the food did not agree the breathing became difficult, and there was violent beating of the heart with increased lividity. The child was seen once or twice by Dr. Peacock, and then not for several years until its last illness. This began on August 8 with earache and restlessness, followed by loss of power in the right hand. In the afternoon of the 9th he had violent shaking of the right arm and hand, and the following morning of the right leg also, with twitching of the right side of the face, and the right arm and leg were powerless afterwards. On the evening of the 12th the temperature was 101°; on the 22d he had a general convulsive fit, followed by partial stupor; on the 23d he recovered consciousness and could speak, though he did not articulate distinctly; on the 24th he had a second attack of convulsions, after which he was entirely unconscious, and he gradually sank till he died at 11 P.M. on the same day. He was six years and nine days old at the time of his death.

EPITHELIOMA OF THE RECTUM REMOVED AFTER A NEW PLAN WITHOUT INJURING THE SPHINCTER ANI—RECOVERY.—The following case occurred under the care of Mr. Rouse, at St. George's Hospital, and is reported in the *Lancet* (vol. ii., 1880, p. 540). The patient, who was 64 years of age, showed an epithelioma of the rectum of about six months' growth, situated on the left side of the bowel, about one inch above the anus. The growth was flat, sessile, about the area of half a crown, and limited to the mucous membrane and the submucous tissue. The deeper parts felt apparently uninvolved. The operation was as follows. A curved incision an inch and a half in length was made, just outside of the external sphincter and parallel to the outline of that muscle. The skin was then dissected upwards and outwards for a short distance, so that the outer circular fibres of the sphincter were exposed. The muscle was then drawn over towards the middle line. By introducing the finger into the rectum the growth was pressed into the external wound, and it was then cut out, together with that part of the wall of the rectum to which it was attached. In this way an opening about the size of half a crown was made through the bowel. After the closure of the skin-wound but a small cavity could be felt, corresponding to the former situation of the growth. The hemorrhage was very slight. Opium was given in order to keep the bowels confined for some days. The recovery was almost uninterrupted. For some few days slight feculent discharge took place from the wound, but after about three weeks this had completely ceased, and the patient then had entire control over the contents of the rectum. As a matter of fact, scarcely any fæces escaped, but the suppuration resulting during the granulation and closure of the cavity possessed a fecal odor. When the patient left the hospital, about a month after the operation, the power of the sphincter was perfectly normal. The general symptoms were much relieved.

The advantages of this method of operating are, remarks Mr. Rouse, obvious, and there seems no reason why it should not be applicable to growths of a much larger size. The advantage of preserving the sphincter intact is evident, and this operation might be advantageously substituted for excision of the lower end of the bowel. Instances have been recorded where that operation has not been followed by incontinence of fæces; but the operation above detailed is certainly preferable.

PREPARATIONS OF TAR.—Dr. Gérard (*Le Progrès Méd.*, 1880, p. 784) thinks that emulsions of tar are the best preparations of this substance for medical use, both internally and externally. Here the tar is suspended in a state of minute subdivision. The old *eau de goudron*, or tar-water, of the French Codex, was too readily alterable to form a trustworthy and efficacious medicine, and in addition the tar existed in such minute quantity that, although exalted at one time as a panacea, it fell out of use after a while altogether. Meantime, efforts were constantly made to obtain a more concentrated solution of tar. Sometimes these took the form of solutions in alkalies, and at other times of ordinary solutions concentrated. But the addition of an alkali changes the effect of the tar, and the mixture thus made cannot take the place of tar alone, while in the act of maceration or concentration in a water-bath the volatile and

bitter constituents of the tar are lost. In consequence of this difficulty in making satisfactory solutions of tar, M. Lebœuf devised a process by which an emulsion containing the active ingredients of tar could be obtained. The substance used for this purpose is saponin, a perfectly neutral substance, prepared, as is known, from the *quillaya saponaria*. As contained in the tincture of the root, which is used in making the emulsion, not enough saponin can be taken to produce toxic effects. It is not difficult to take, and is comparatively easy of digestion; while the capsules of tar are apt to embarrass digestion and cause headache.

Autopsies in the Parisian Hospitals.—Recent French laws relative to the disposal of the dead appear to bear rather hardly on the interests of scientific medicine. In the first place, interments may not take place until twenty-four hours after decease. This is to prevent burying alive, and is thus far good. But the "ordonnance" concerning autopsies, embalmment, etc., goes on to forbid any such operation until twenty-four hours have elapsed after decease. It is also necessary to place before the authorities evidence that the operation, whatever it may be, is authorized by the family. These regulations are said not to be applicable to operations practised in hospitals or legal dissecting-rooms. Further regulations, however, are provided for these. Thus, professors and hospital surgeons may proceed to open a cadaver, but may not dissect it. Hospital physicians, other than the clinical professors, may make autopsies on only one-third of the patients dying under their care. Corpses reclaimed by their families may not be examined. Autopsies may not be made until twenty-four hours have elapsed since death (!). In some cases this law against inhumation before twenty-four hours, if carried out strictly, may do harm, *e.g.*, in persons dying with smallpox; while in cases where autopsy may be desired, a delay of twenty-four hours may cause such alteration in the tissues as to disguise entirely the early post-mortem appearances.

Fatty Tumor beneath the Scalp.—Mr. Sydney Jones (*Lancet*, vol. ii., 1880, p. 587) reports the case of a boy of 20 months, on whose scalp, at the age of two months, a tumor the size of a marble was noticed. It increased at first slowly, but later rapidly, until, when the child was brought to Mr. Jones, the tumor was the size of half an orange. It occupied the median line, was over the sagittal suture, and extended backwards to the situation of the posterior fontanel. Pressure caused no diminution in size, head-symptoms, or other inconvenience; crying made it tighter and more prominent. The margin was raised, and harder than the rest of the tumor. A small portion of the tumor removed with the grooved needle showed fatty particles under the microscope. The tumor was transfixed longitudinally and removed. It was adherent in some places to the scalp, and was accurately moulded to the pericranium, from which it was pulled off. The tumor weighed two and a half ounces, and consisted of pure fat. The wound healed without trouble.

Locomotor Ataxy in Various Members of the same Family.—At a recent meeting of the Clinical Society of London (*Lancet*, vol. ii., 1880, p. 618), Dr. Gowers brought forward a series of five cases of locomotor ataxy in members of the same family, three of whom were exhibited. The father was healthy, but his brother and two half-cousins were insane. The mother had suffered in early life from cholera. The family consisted of nine children: (1) a son, aged thirty-nine, with well-marked ataxy, which commenced at nineteen. He is just able to walk with crutches. There is incoördination in the arms, with affection of articulation. Sensation to touch is normal, that to pain in the legs is increased. The knee-jerk is lost. (2) A girl, who died of fever at ten years old. (3) A son, aged thirty-five, healthy. (4) A son, aged thirty-three, healthy. (5) A girl, aged twenty-nine, in whom the affection commenced at eighteen. She can now scarcely stand; there is weakness in the legs, as well as ataxy, and also incoördination in the arms. Speech is affected, sensation is normal, the knee-jerk lost. (6) A son, aged twenty-six, perfectly well. (7) A son, aged twenty-three, considerably affected. The disease showed itself at nineteen; he is now scarcely able to walk, with ataxy of both arms and legs, and loss of sensation, absence of knee-jerk, and affection of articulation. (8) A son, aged twenty-two, reported to be well, but found, on examination, to be distinctly affected. Articulation is confluent, there is inability to stand with the eyes shut, absence of knee-jerk, and distinct impairment of sensation on the legs to touch. The arms are at present unaffected. (9) A son, aged nineteen, affected in rather a greater degree than the last, with slight unsteadiness of gait, inability to stand with eyes shut, distinct impairment of sensation to touch, absent knee-jerk, unsteadiness in writing, and confluent articulation. Thus, of eight members of the family who have reached adult life, five are affected. The only causal influence discoverable is the neuropathic heredity. Several similar groups of cases have been reported. It is noticeable that none have suffered from pains in the limbs. There is no affection of the iris or of the optic nerve. In previously reported cases where autopsies have been had, the lesions found have been similar to those of ordinary ataxy.

Blue Spots on the Skin Symptomatic of Phtheiriasis Pubis.—The occasional occurrence of blue, slate-colored, or dark spots on the skin, of a mysterious character, has long

been exercising the minds of our French brethren, who have written long articles to show the exact significance of these mysterious patches and the mode of their production. From an investigation of two hundred and fifty cases in 1878, Moursou found that they were invariably accompanied by crablice. Recently, Dr. Duguet (*La France Méd.*, 1880, p. 610) has produced these blue spots by inoculating various portions of the skin with a paste made of the pediculi ground up with water. The day after inoculation very well marked blue patches, the size of a ten-cent piece, were noticed at each point operated upon. These patches lasted several days, then began to fade, and by the end of ten days had entirely disappeared.

PROGRESS IN THE TREATMENT OF STRICTURE OF THE URETHRA.—Some remarks were made on this subject by Sir H. Thompson, at the annual meeting of the British Medical Association, in Cambridge, August, 1880. As illustrations of this advance during the last thirty years in England, the doctor mentioned five points:

1. A general recognition of the principle that a delicate and gentle manipulation of any instruments in the urethra is alone trustworthy or permissible, in the place of that which was formerly greatly prevalent, viz., that urethral obstruction might often be overcome mainly by force.

2. The substitution of very pliable and taper instruments for silver and stiff gum-elastic instruments in much of the treatment, both in ordinary and in continuous dilatation.

3. A more general acceptance of the doctrine that, given time, patience, and gentle handling, very few strictures should be met with which cannot be fairly and successfully traversed by an instrument passed through them into the bladder. At the same time, an undoubted improvement is to be noted in the mode of operating for those exceptional cases in which the surgeon fails to accomplish that object.

4. A more general acceptance of the doctrine that dilatation of the urethra, whether with or without incision, may be carried with advantage to a somewhat higher degree than had for some time previously been regarded as desirable.

5. The substitution of internal urethrotomy in some form for the application of caustics, and for external urethrotomy on a guide.

Each of the topics named is then considered somewhat in detail. In connection with the subject of the "calibre," or "diameter," of the urethra, or the amount of its dilatability, he refers to Dr. Otis's revival of the theory of "the large diameter of the urethra." He records his sense of the value of this point, but he adds that "it is a very easy thing to damage irreparably some individuals by overdistending the urethra." Thompson also opposes another doctrine which is associated with the preceding, viz., that stricture of the urethra is permanently cured by complete division of all the diseased tissues affecting the passage. In speaking of the many methods of performing internal urethrotomy, he says that the principles which govern a sound procedure are more essential points for the surgeon to discover and to teach than a consideration of small details. These principles he briefly states as follows. 1. The necessity for a physical examination before operating, to detect and estimate the narrowed portions of the urethra. This is best accomplished, in his opinion, by means of a series of metal bulbs on slender stems, taking care not to regard as changes of disease those points at which the urethra itself is naturally only slightly dilatable. These bulbous exploring sounds he invariably used, advocating them as essential to diagnosis, in his first work, twenty-six years ago. He still prefers them to any others, as safer, less irritating, and not less efficient than more complex instruments which have been devised. 2. The necessity for accomplishing a complete division of all the morbid tissue constituting the stricture, by an incision carried through it, no matter what part of the urethra, or how much of it, is involved in the disease. As a general rule, he thinks, this is most efficiently done by a slender blade, carried beyond the stricture and made to cut from within outward, this latter proviso being, however, an open question. The important point is that any alleviation of the patient's condition attained by operation will be transitory if any part of the narrowing be left undivided. 3. He regards it as essential, after such division, to place at once a full-sized catheter for some hours in the bladder, to insure a free outlet for the urine, and prevent all possibility of extravasation of urine into and through the incisions thus made. 4. The necessity for passing full-sized bougies subsequently, at occasional intervals, in order to effect free distention of the walls of the urethra, which lie in almost constant apposition, and so to prevent reunion of divided surfaces by the first intention. Finally, he declares that the great desideratum of the present time unquestionably is the discovery of a mode of treatment which shall permanently restore to the strictured passage its original dilatability; and he adds that a thoughtful consideration of the pathological condition which constitutes organic stricture does not embolden him to hope that such a result can be insured by the application of any principles of action at present known to us.—*The British Medical Journal*, August 28, 1880; *New York Medical Record.*

CASTRATION FOR HYSTERIA.—Under this title the *Lancet* (vol. ii., 1880, p. 588) gives a curious story of an hysterical patient who had suffered for some years from obstinate vomiting, accompanied by severe ovarian pains. She became extremely weak, and finally con-

sented to spaying as the only hope. The operation, which was performed under chloroform with "antiseptic precautions," was a mockery, the skin only being incised. A perfect cure, however, of all the hysterical symptoms resulted.

ERRORS OF CLINICAL THERMOMETERS.—It may not be generally known that the clinical thermometers in common use are not to be relied upon within one-half a degree Fahrenheit. Thermometers having a Kew certificate less than six months old are excepted. A thermometer which may be accurate when first made may afterwards change, and new thermometers should be laid aside for two years before they are fully graduated. The error is in an increase of reading; eighteen months may permit a rise of .4° Fahrenheit.

GASTROTOMY.—Dr. Elias reports in the *Deutsche Med. Wochens.* (No. 25, 1880) a very successful case of gastrotomy in a man aged 48, reduced to the last extremity by stricture of the œsophagus. The collapsed stomach was with difficulty found during the gastrotomy; it was fastened to the abdominal wall and opened on the fifth day, when union was complete. Twelve days after the operation the patient was able to go out, and the nutrition of the body rapidly improved.

REMOVAL OF THE ENTIRE SCAPULA.—Mr. Bellamy, of Charing-Cross Hospital, recently removed the scapula for an encephaloid growth involving the whole bone. The hemorrhage was but trifling, owing to the perfect command obtained over the subclavian artery by compression through a primary incision in the integuments. A week after the operation the patient was progressing satisfactorily.—*Lancet*, vol. ii., 1880, p. 588.

TREATMENT OF THE VOMITING OF PREGNANCY BY ETHER SPRAY.—Dr. Lester writes to the *New York Medical Record* giving a case of uncontrollable vomiting, in which, after everything else had been tried, he conceived the idea that freezing the pneumogastric near its origin might possibly control the intensely-irritable stomach. In view of this fact, he at once commenced the process of freezing the nerve in its track, under the sterno-mastoid, on both sides of the neck alternately. The effect was, indeed, remarkable, for decided benefit was observed after the first trial, and during the first twenty-four hours the woman vomited only four times, and in three days the vomiting ceased entirely. This process was performed every two hours the first day, and at much longer intervals during the second and third days, and continued ten minutes at each sitting. The pulse was closely observed.

STATE OF THE GANGLIONIC CENTRES IN BRIGHT'S DISEASE.—Drs. Longstreth and Da Costa, in a paper on this subject in the *American Journal of the Medical Sciences* for July, 1880, conclude as follows:

1. That in Bright's disease, especially in the contracting kidney, there exists a constant lesion of the renal plexus.

2. That whilst this lesion might be looked upon as forming part of a general process of degeneration, in connection with the kidney disease, we think it is the cause of the renal malady, and precedes the degenerative changes.

3. That the diseased condition of the ganglia furnishes the clue to the alterations of the vessels of the kidneys.

4. That similar changes producing similar results may exist in other ganglia; for instance, in the cardiac plexus, explaining the hypertrophy of the heart.

MISCELLANY.

ACTINOMERIS HELIANTHOIDES.—The root of actinomeris helianthoides is from the size of a quill to that of a knitting-needle, and has an oil and perhaps a resin in it, giving it the taste and somewhat the smell of turpentine. It has long been used by the people of Upper Georgia in dropsy, under the name of diabetes weed. Dr. I. G. M. Goss says that he has used it in several obstinate cases of dropsy and in several cases of chronic cystitis with fine effect; also in calculous affections and in chronic inflammation of the entire urinary tract. He gives it in the form of a tincture, one or two drachms to a dose, as a diuretic, or as an infusion, in doses of one-half to one ounce, repeated every hour or two. It may be tinctured in sweet spirit of nitre, eight to sixteen ounces of nitre.—*New York Medical Journal.*

QUININE-PRODUCTION IN INDIA.—Experiments in acclimatizing the cinchona-tree in India have been entirely successful, and there are now, in various stages of growth, probably millions of cinchona-plants already yielding the Peruvian bark so plentifully and perfectly that the price of quinine has fallen in Ceylon and other parts to about eighty cents an ounce. There appears reason to believe that, sooner or later, quinine may be exported from that country.

CONVERGENT SQUINT.—Dr. C. A. Bucklin (*New York Medical Record*, vol. xviii., Nos. 4 and 16), in an article on the cause, results, and treatment of this deformity, recapitulates as follows:

1. All persons squint who can see by doing so and cannot see without. The degree of their hyperopia or the strength of their internal muscles can be what they may.

2. Every squinting eye that is not due to *paralysis* of a muscle can be straightened.

3. Never fail to satisfy yourself, before leaving an eye you have tenotomized, that the mobility of the eye is sufficient.

4. The use of one eye is usually lost in convergent squint; consequently its earliest symptoms should receive prompt attention.

RED PERSPIRATION IN THE AXILLÆ.—A correspondent of the *New York Medical Record* of October 30, referring to a case of this sort recently reported in that journal, says that he is himself a subject of the same phenomenon. Although he perspires greatly in summer, the red perspiration occurs only now and then, he thinks, after taking an unusual amount of exercise. He has never known the red perspiration to occur except in summer. The hairs of the axillæ are matted together with a honey-like secretion, which is quite sticky.

THE MARRIAGE AGE IN DIFFERENT COUNTRIES.—Austria, 14 years for both sexes; Germany, the man at 18, the woman at 14; Belgium, the man at 18, the woman at 15; Spain, the man at 14, the woman at 12; France, the man at 18, the woman at 15; Greece, the man at 14, the woman at 12; Hungary, Catholics, the man at 14, the woman at 12; Protestants, the man at 18, the woman at 15; Portugal, the man at 14, the woman at 12; Russia, the man at 18, the woman at 16; Saxony, the man at 18, the woman at 16; Switzerland, the man at 14, the woman at 12; Turkey, at puberty.—*Medical Gazette.*

MORTALITY AMONG MEDICAL MEN.—Hecker confirms by his statistics a fact, indeed, already known, that the duration of life among medical men is notably less than the mean. From Escherich's statistics it results that in Bavaria, of 100 individuals, 53 Protestant pastors, 41 professors, 39 advocates or magistrates, 34 Roman Catholic priests, and only 26 doctors reach the age of fifty.

EUCALYPTUS OIL FOR DRESSINGS.—Dr. Schulz, of Bonn, considers that eucalyptus oil offers many advantages over carbolic acid, without its inconveniences. It is a powerful antiseptic, is freely soluble in alcohol and oil, and mixes well with paraffin; its odor also is agreeable. Dressings prepared with this oil are very antiseptic. It may be employed also for spray and washing.

CHANGES OF COLOR IN SKIN AND HAIR.—Smythe (*Archives of Dermatology*, July, 1880) tells of a man of 47 who had, up to his thirty-fifth year, a fair skin, with light hair and dark eyes. About this time his hair began to turn gray, but the hair which did not turn gray turned to nearly a jet-black; his skin at the same time assumed a dark and bronzed hue.

TREATMENT OF SYPHILITIC NEURALGIA.—M. Mauriac treats the neuralgia symptomatic of syphilis with iodoform pills, according to the following formula:

℞ Iodoform powder, 1½ gramme;
Extract and powder of gentian, q. s.

Divide into 20 pills, two or three to be taken daily.

THE London *Lancet* characterizes London as a town "where flowers cannot be made to grow, where sunlight is a rarity, where all we touch is smutty, and where the very statues in the streets succumb to the biting acidity of the atmosphere."

DR. EDWARD SEGUIN died in New York October 28, in the 69th year of his age. He was especially famous for his efforts in behalf of idiots, and is said to have founded no less than eleven schools for their treatment and education in the United States.

WE are surprised to read in the *New York Medical Record* of October 30 that Dr. Austin Flint, Jr., has declined the Chair of Physiology in the Jefferson Medical College. As no vacancy exists in the said chair, our cotemporary must be wool-gathering.

MELOHIAH, a Choctaw princess, died at Hoyt City, in the Indian Territory, the other day, at the great age of 114 years. She had thirteen great-great-grandchildren. She had been addicted to the inordinate use of tobacco for one hundred and five years.

EFFORTS are being made to secure a law in Pennsylvania similar to that in force in New York for the purpose of guarding the inviolability of confessions made to physicians or secrets discovered in the course of medical attendance.

LACTIC ACID IN CHRONIC CATARRH OF THE BLADDER.—Deeke recommends injections of a one-half- to one-per-cent. solution of lactic acid in cystitis with ammoniacal urine.

APPROPRIATE.—We notice a paper on post-partum hemorrhage, by Dr. *Gore*, in the *St. Louis Medical and Surgical Journal* of October 20, 1880.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM OCTOBER 31 TO NOVEMBER 13, 1880.

KING, WILLIAM S., COLONEL AND SURGEON.—His leave of absence still further extended six months on account of sickness. S. O. 240, A. G. O., November 9, 1880.

MEACHAM, F., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 234, A. G. O., October 30, 1880.

PATZKI, J. H., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty at Jackson Barracks, La. S. O. 126, Department of the South, October 29, 1880.

HEITZMANN, CHARLES L., CAPTAIN AND ASSISTANT-SURGEON.—The extension of his leave of absence of September 28, 1880, from Headquarters, Division of the Pacific and Department of California, is further extended two months. S. O. 234, c. s., A. G. O.

LAUDERDALE, J. V., CAPTAIN AND ASSISTANT-SURGEON.—Relieved from duty as Post-Surgeon at Newport Barracks, Ky., and assigned to duty at McPherson Barracks, Ga. S. O. 127, Department of the South, November 1, 1880.

WORTHINGTON, J. C., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for six months. S. O. 241, A. G. O., November 10, 1880.

WOOD, M. W., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to duty at Fort Brady, Mich. S. O. 201, Department of the East, November 12, 1880.

SATTERLEE, RICHARD S., LIEUTENANT-COLONEL AND BREVET BRIGADIER-GENERAL, Chief Medical Purveyor of United States Army (retired).—Died at New York City November 10, 1880.

PHILADELPHIA, DECEMBER 4, 1880.

ORIGINAL COMMUNICATIONS.

IMPRESSIONS OF VIENNA AS A MEDICAL SCHOOL.

BY ROBERT W. JOHNSON, M.D.,
Baltimore, Md.

So common is it now for American students of all departments to go to Continental or English universities in the hope of gaining knowledge they think unattainable on this side of the Atlantic, that it may not be uninstructive to those who seek medical advantages abroad to learn a few of the particulars of the Vienna hospitals and their modes of teaching.

Having had the good fortune to be there for some months, and deploring my bad luck in not remaining as many years, I mean in this paper to lay before men similarly situated some hints that will aid them, I hope, in spending their time there to the greatest advantage; for I found that it takes the average man about a month, even if familiar with German, to acquaint himself sufficiently with the various workings of the larger institutions to put in his labor where he will reap the greatest reward. Before entering on the subject proper of this paper, it may be asked, "Is it worth while for a physician to go abroad? Will he be compensated for the time he spends and the expense incident to the trip? Can he not learn just as much of his profession in our own great cities?"

The first question may be answered in the affirmative, if he can afford to put the actual money down, even with an economical pinch, for the benefit is to the man as much as to the doctor, and his education is brought nearer completion by the civilization and traditions, the history, arts, and literature, of the Old World, and he is less of a machine than are so many backwoodsmen, who with but little previous instruction pass the atrophic examinations of some two-year medical school, whose "Dr." is synonymous with debtor, and who, it may be, finally reach a professorship in a similar institution or seek another level in pot-house politics.

Can one learn as much in America as abroad? Such is the never-ending expanse of knowledge in medicine and its ramifications that we can learn in one city far more than most of us can retain, but it must be conceded to Vienna that her accommodations for learning exceed aught that I have seen either in London or in our own country. There is a greater centralization of our science, a community of teachers, a classification of the three thousand patients that supply the beds and dead-house of the "Allgemeine Krankenhaus" or general hospital, than is afforded, to the best of my knowledge, under any other roof in the world. In six months one can learn more of the specialties taught there than elsewhere in two years, unless he have more than ordinary privileges. Just as an author seeks a library to refresh his memory or refer to authorities, so it behooves us when learning disease to seek those places where the best types and opportunities obtain; where the books of nature unfold her laws either on the tables of stone in the dissecting-room or in the equally legible physical examination in the ward.

This centripetal institution contrasts most favorably with some centrifugal schools at home, which, like some theatres, possess one or two stars or fine properties, while the other attributes of success are lamentably wanting. *Eclat*, never a just incentive to foreign study, does not now exist, for our countrymen have been so much abroad, and have seen so many of their fellow-citizens go, that a physician must have a further and better claim on the confidence of the laity than, to use their own expression, to have "walked the hospitals of Paris or Edinburgh." Berlin, Edinburgh, London, Paris, and Vienna are the chief medical centres that divide the attention of Americans; and while Dublin with the obstetric department of the Rotunda, Strasburg with pathology, and Halle with Volkmann to preach and practise Mr. Lister's method almost better than that great surgeon himself, all claim a share of the much-desired American patronage, with concomitant Yankee gold, still the above-mentioned cities almost monopolize scientific birds of passage.

From personal experience I can only compare Vienna with London, and I shall endeavor to show why the Austrian capital is preferable. "Figures do not lie;" but unless one knows all the circumstances entering statistical arithmetic, they may

be omitted with advantage; so, should the reader expect a series of vulgar fractions or a rule of three in which the physician, result, and patient are the known quantities and nature plays her customary rôle incog., he must look elsewhere for his gratification. Suffice it to say that the available beds in Vienna hospitals reach at least four thousand, and the number of patients, including various dispensaries, send several times that number to the clinics. The great feature about Vienna is, that about three thousand of these beds are in one hospital and furnish material for lectures on every specialty that is anywhere taught. There are two distinct classes of students attending the almost equally distinct classes of teachers, though of course there are exceptions, no rule preventing a man from listening to whomsoever he please.

First, let me mention the lectures, theoretical and clinical, which are given by the professors, more especially to men seeking a degree from the University. The second division of clinics and courses is more patronized by our fellow-countrymen. These practical courses are a series of thirty or forty demonstrative lectures in which there is an explanation of the subject in hand, together with a selection of cases which illustrate its various phases, and each man in the class has a chance to examine the patient and appreciate for himself the actual lesion described by the instructor. The number of students in some is limited by the accommodations or the intricacy of the topic, and it is always advisable to secure a class that is not overcrowded, for the more special attention one gets the more at home he will be with the subject. The teacher is most often the assistant of the professor, attends to his wards, and consequently one gets from him diagnosis and treatment of the first quality, though it comes second-hand. Instruction is not limited to the living patient; there are valuable courses also on anatomy, operations on the cadaver, pathology, microscopy, etc. They are often so arranged that a man can fill the whole day with separate subjects, each lecture lasting one hour and in close proximity to each other, thus avoiding loss of time in transit; but beware of the literary dyspepsia that a young and enthusiastic scientific gourmand can easily acquire in such "a feast of reason and flow of soul." He will find a simple and nutritious diet far more conducive to his growth in professional knowledge.

Not a few of the instructors speak English fluently, and one went so far as to give a course in English; but it is no small benefit to obtain a knowledge of German, and though it may be pleasing to hear one's mother-tongue, it is far more profitable to wrestle with the vernacular, as it is only by unalloyed perseverance, and a perfect complacency in regard to errors, that its difficulties can be overcome. The plan I found most beneficial, and one that I would recommend to medical students who are obliged to leave home to attend lectures, is to board with an intelligent German family, a Hanoverian preferred, with young children who speak simply, and learn from them by daily practice at table, and on every other occasion, as much of the desired language as possible.

The man who does this not only overcomes the hesitancy natural at the outset, but picks up a great many phrases and idioms, as well as the pronunciation, which is the "pons asinorum" to even good German scholars who can read readily.

Should he desire to study and read German, he will find it greatly advantageous to invest in little plays, for in them we get every-day expressions and colloquial phrases, avoiding the ridicule which we bestow on a foreigner who talks Shakspeare or writes *à la* "Faërie Queene." One thing, however, you may rely on, and that is the most stolid indifference to mistakes, for I have seen the saleswomen look as sober in a bakery when I asked for a countess instead of a cake as though they had been agents for "Burke's Peerage" instead of dispensers of the delicious *mehlspeisen* for which Vienna is justly noted.

Those who begin to study German in Europe find the best in Hanover or Brunswick; but let not the heart of the student be troubled because his ears, tuned to polished pronunciation, fail to receive the slushy accents of Viennese dialect. He will soon learn that "heit" means heute, and the mädl will be no less fair because she has fallen from the more dignified and high estate of mädchen. While German is essential to understanding the lectures, you need not fear to go to Vienna without it, for by taking a few of the practical courses, where the hands are used as much as the tongue in study, you can acquire a knowledge of the language in the kindergarten

style that will soon render you fit to sit at the feet of any Gamaliel there; nor is this less easy to see when you remember that, in spite of German individuality, a great many terms in medicine are common to all languages, while the subject-matter should be familiar to you to a certain extent before you leave home.

Not far from the General Hospital are the Polyclinic, a large dispensary with separate rooms for clinics in different branches, and the St. Anna's Children's Hospital. The material at the former is transitory; at the latter there are beds where the more serious diseases of childhood can be observed.

Rudolph's Hospital and several others might be enumerated, but the above are the principal. In my *résumé* below I shall mention the men I would recommend as instructors, including gentlemen at these institutions as well as those of the larger General Hospital. There is such an opportunity for choice in all branches that I will underscore those whom my friends or myself found satisfactory, in order that the student visiting Vienna may not lose time in making his selection; but it must not be understood that the men not emphasized are necessarily secondary, because with many of them I did not come in contact.

The title of professor there is not, as it is so often with us, a reflex one, if I may use that expression entirely independent of brain, but it means something when conferred and not assumed, so that I feel peculiarly humble in criticising those who enjoy that distinction, though even in Olympus there is a choice. It is well, too, for a man to hear them all a few times, and decide for himself, since the clinics by professors when compared to the courses are not numerous, and it adds much to the pleasure of reading a scientist's deductions if we have seen him face to face in the flesh.

Below will be found the official schedule of the lectures, together with the number of hours devoted per week to each class; but the reader must know that changes continually occur, and the catalogue may be found wanting even during the year for which it is intended; but, as it gives a nearer approach to facts than can be elsewhere obtained, it is offered with such amendments as the user will find necessary when there.

SCHEDULE OF LECTURES IN THE UNIVERSITY OF VIENNA (MEDICAL DEPARTMENT) FOR THE WINTER SEMESTER 1879–1880.

Time. A.M.	Subject.	Hours per week.	Instructor.	Remarks.
8 – 9	Theoretical and Practical Ophthalmology	5	*Prof. von Jaeger.*	
	Auscultation and Percussion	5	*Dr. Kolisko.*	
	Diagnosis of Eye Diseases	5	*Dr. Bergmeister*	Especially diseases of anterior portion.
	Gynæcology	5	Dr. Schlesinger.	
	Throat and Chest Diseases, Polyclinic	6	*Prof. Schnitzler.*	
	Practical Course in Endoscopy, Polyclinic	3	Prof. Auspitz.	
8 – 9½	Hydro-Therapeutics	4½	Dr. Winternitz.	
8 –10	Special Medical Pathology—Therapeutics and Clinic	10	*Prof. Duchek.*	
	" " " " "	10	*Prof. Bamberger.*	
	" " " " "	10	Prof. Loebel.	
	Clinic for Skin Diseases	10	*Prof. Hebra.*	
	Special Surgical Pathology and Therapeutics	10	Prof. Dittel.	
8½–10	Instruments and Bandaging	3	Prof. Cessner.	
9 –10	Human Anatomy—Bones, Muscle, Intestines	6	Prof. Langer.	
	Casuistic Gynæcology	1	Prof. C. von Braun.	
	" "	1	Prof. Spaeth.	
	Eye Clinic	5	Prof. von Jaeger.	
	Electro-Therapeutics	5	Dr. Schultz.	
	Theoretico-Practical Ear-Surgery	5	*Prof. Gruber.*	
	Diseases of Women	5	*Dr. Bandl.*	
	Laryngoscopy and Throat-Therapy	5	*Prof. Schnitzler.*	
	Physical Diagnosis—Pneumato-Therapy	1	" "	
	Syphilis and Skin, Polyclinic	5	*Prof. Auspitz.*	
9 –11	Lessons in Obstetrics	10	Prof. G. Braun	For midwives.
	Psychological Clinic	4	Prof. Schlager.	
	Diseases of Prostate and Urethral Stricture	4	*Prof. Dittel.*	
	Gynæcological Dispensary	2	Dr. Chrobak.	
	Practical Exercise in Pathology and Histology	6	Prof. Klob.	
10 –11	Pharmacy	5	Prof. Vogl.	
	Gynæcological Course	5	Dr. Funk.	
	Nervous Diseases and Therapeutics	5	Dr. F. Fieber.	
	Skin Diseases	5	*Prof. Kaposi.*	
	Internal Medicine, Polyclinic	3	Dr. Winternitz.	
	Diet-Cure	1	" "	
	Embryology	2	*Prof. Schenk.*	
	Pathological Anatomy of Respiratory and Circulatory Organs	3	Prof. Klob.	
	Laryngoscopy	6	Prof. Schrötter.	
	Diseases of Bones and Joints	3	Dr. Weichselbaum.	

Time. A.M.	Subject.	Hours per week.	Instructor.	Remarks.
10 –11	Gynæcology	6	*Dr. Rokitansky.*	
	Lectures on the Eye	2	Dr. Hock.	
10 –11½	Respiratory and Circulatory Diseases	3	*Dr. Heitler.*	
	Pathology and Therapeutics of Consumption	3	Dr. Bettelheim.	
	Minor Surgery with Practice	5	*Dr. Hofmokl.*	
10 –12	Surgical Clinic	10	*Prof. Dumreicher.*	
	" "	10	*Prof. Billroth.*	
	Theoretical and Practical Ophthalmology	10	Prof. von Arlt.	
	" " "	10	Prof. von Stellwag.	
	Structure and Action of Central Nervous System	2	Prof. Meynert.	
10½–11½	Polyclinic of Eye Diseases	5	Dr. Hock.	
	Diseases of Children	6	*Dr. Monti*	Lecture and clinic.
11 –12	Physiology and Higher Anatomy	5	Prof. Brücke.	
	Veterinary Course	3	Prof. Röll.	
	Diseases of Children	5	*Prof. Widerhofer*	Lecture and clinic.
	Laryngo-Rhinoscopy	5	Prof. Störk.	
	Lectures on Diseases of Female Genitals	2	Dr. Funk.	
	Diseases of the Kidneys	2	Dr. Breuer.	
	Manikin-Practice for Midwives	5	Drs. Felsenreich and Borns.	
	Auscultation and Percussion	5	Prof. Schrötter.	
	Demonstrations of Pathology, Anatomy, and Post-Mortems	5	*Dr. Chiari.*	
	Pathological Anatomy of Syphilis and Tuberculosis	1	" "	
	Forensic Psycho-Pathology	2	Prof. Leidesdorf.	
11 –12½	Orthopædic Surgery	1½	*Dr. Nicolodoni.*	
	Diseases of Stomach and Bowels	1½	Dr. Osor.	
11 – 1	Physical Examination	4	Prof. Stern.	
	Surgical Course (*Propädeutic*)	4	Dr. K. Fieber.	
	Male Genito-Urinary Diseases	4	Dr. English.	
	Electro-Therapeutics	2	Prof. Benedikt.	
	Operative Dentistry	2	Dr. Steinberger.	
11½–12½	Diseases of the Urinary Organs	5	*Dr. Ultzman*	With analysis of urine.
11½– 1 P.M.	Diseases of Brain and Spinal Cord	1½	Prof. Benedikt.	
12 – 1	General and Special Pathology, Anatomy, and Histology	5	*Prof. Heschl.*	
	Clinic on Nervous Diseases and Psychology	5	*Prof. Meynert.*	
	Pathology and Treatment of Nervous Diseases	5	Prof. Rosenthal.	
	Aural Surgery, with Cases	5	*Prof. A. Politzer.*	
	Operative Surgery on Cadaver	6	*Dr. Hofmokl.*	
	Surgical Bandaging	5	*Dr. Nicolodoni.*	
	Percussion and Auscultation	3	Dr. Rollet.	
	Practice in Diagnosis and Treatment of Nervous Diseases	5	Prof. Benedikt.	
12 – 1½	Medical Physics	4½	Prof. Schwanda.	
12 – 2	Gynæcologico-Obstetrical Clinic, with Treatment of Infantile Disease	10	*Prof. K. Braun.*	
	Gynæcologico-Obstetrical Clinic, with Treatment of Infantile Disease	10	*Prof. Spaeth.*	
	Exercise in Pathological Histology	14	Dr. Weichselbaum.	
	Operative Gynæcology	6	*Dr. Bandl.*	
12½– 1½	Treatment of Children	5	Dr. Hüttenbrenner.	
	Diseases of Children	3	Prof. Politzer.	
	Treatment of Children	3	Dr. Eisenschitz.	
1 – 2	General Pathology	5	*Prof. Stricker.*	
	Histology	3	Prof. Wendl.	
	Demonstrations out of the Domain of General Pathology	1	" "	
	Lectures on Health-Resorts	2	Prof. Seegen.	
	Physiology and Pathology of the Central Nervous System	3	Dr. Oberstriner.	
1 – 2½	Practical Histology	3	Prof. Wendl.	
	Practice in Microscopy	9	Prof. Exner.	
1 – 3	Genito-Urinary Surgery	4	Dr. Jurié.	
	Medical Jurisprudence	5	Prof. Hofmann.	
	Pharmacology	3	Prof. Vogl.	
	Symptomatology	2	Prof. Stern.	
	Practical Use of the Microscope	3	Prof. Schenk.	
	Polyclinic of Eye Diseases	5	Dr. Reuss.	
	Diseases of the Skin	5	*Dr. Hebra.*	
	Special Pathology and Treatment of Internal Diseases	5	Prof. von Stoffella.	
	Diagnosis of Internal Diseases	5	Dr. N. Weiss.	
2 – 4	Practical Hygiene	10	Prof. Nowak.	
	Treatment of Eye Diseases	10	Prof. Mauthner.	
	Practical Hygiene	10	Dr. Kratschmer.	
2 – 6	Practical Medical Chemistry	20	Prof. Ludwig.	
3 – 4	Pathological Dissection	3	Prof. Heschl.	
	Medico-Legal Instruction	2	Prof. Hofmann.	
	Diseases of Children (Youth)	6	Dr. Fürth.	
	Skin Disease and Syphilis	5	*Prof. Neumann.*	
	Vaccination, Suckling, and Nurse-Diseases	2	Dr. Fridinger.	
	Operative Dentistry	2	Dr. Zsigmondy.	
	Dental Surgery	3	Dr. Scheff.	
	Experiments on the Mechanism of Wounds	3	Dr. Schlemmer.	
3 – 5	Dissections and Demonstrations	14	Prof. Langer.	
	Theoretical and Practical Use of the Ophthalmoscope, and Eye-Operations	10	Prof. von Jaeger.	
	Diseases of the Skin	2	Prof. Wertheim.	
4 – 5	Clinic for Syphilis	5	*Prof. Sigmund.*	
	" "	5	Prof. Zeissl.	
	Physiological Psychology	2	Prof. Exner.	

Time. P.M.	Subject.	Hours per week.	Instructor.	Remarks.
4 – 5	Sphygmography	1	Dr. Winternitz.	
	Practice in Examining Patients	1	Prof. Schlager.	
	Lectures on Children	3	Dr. Hauke.	
	Symptomatology ("des Irreseins")	2	Dr. Weiss.	
4 – 5½	Diseases of Stomach and Intestines	1½	Dr. Oser.	
	Diseases of the Ear	12	Dr. Urbautschitsch.	
5 – 6	Epidemiology	4	Prof. Drasche.	
	Special Medical Pathology and Therapeutics	2	" "	
	Obstetric and Gynæcological Operations	5	*Dr. Pawlik.*	
	On Cadaver	.....	*Dr. Welponer.*	
	Systematic Lectures on Gynæcology	4	Dr. Massari.	
	Venereal Therapeutics	2	Dr. Kohn.	
	Syphilis	3	Dr. Vajda.	
	Higher Mathematics for Physicians	3	Dr. von Fleischl.	
	Physiological Consultation	2	" "	
	Internal Medical Percussion and Auscultation	5	Dr. Bettelheim.	
5 – 6½	Physiological and Pathological Chemistry	3	Prof. Ludwig.	
	Mental Diseases	4½	Prof. Leidesdorf.	
	Operative Surgery	3	Prof. Saltzer.	
	" "	3	Prof. Mosetig-Moorhof	
6 – 7	" "	6	*Dr. Nicolodoni*	Also give courses on bandaging, fractures, and plastic surgery.
	" "	6	Dr. Wölfler	
	" "	6	Dr. Mikulicz	
	" "	6	*Dr. Holl*	
All day.	Anatomico-Physiological Work for Beginners	.....	Prof. Brücke.	
	Course in General Chemistry	.....	Prof. Ludwig.	
	Course in Embryology	.....	*Prof. Schenk.*	
	Teeth-Filling and Dental Technics	.....	Dr. Zsigmondy.	
	Work on Pathology and Physiology of Central Nervous System	.....	Dr. Meynert.	
According to agreement.	Special Treatment of Blennorrhagic Affections of Genito-Urinary System	2	Dr. von Vajda.	
	Practice in Diagnosis	5	Prof. Stern.	
	Fractures, Luxations, etc	5	Dr. English.	
	" "	5	Dr. K. Fieber.	
	Surgical Bandaging	5	" "	
	Surgical Anatomy and Operations	5	Dr. Jurié.	
	Physical Diagnosis	5	*Dr. Heitler.*	
	Practice with Ophthalmoscope	5	Dr. Hock.	
	" " "	5	*Dr. Fuchs.**	
	Course on Syphilis	5	Dr. Mrazek.*	
	Course on Operations on the Eye	5	*Drs. Denk* and Borysiekiewicz.**	
	Skin Disease	5	Dr. Jarish.*	
	Diseases of the Ear	5	Dr. Poilak.*	
	†"Touch Course"	6	*Dr. Pawlik.*	
	" "	6	*Dr. Welponer.*	
	" "	6	Dr. Kucher.	
	" "	6	Dr. Schauta.	
	Operative Obstetrics on Cadaver	5	Dr. Kucher.	
	" " "	5	*Dr. Schauta.*	
	Methods of Chemical Analysis	6	Prof. Ludwig.	
	Physical Diagnosis	6	Drs. Kretchy and Brenner.	
	" "	6	Drs. Lützen, Müller, and J. Kauders.	
	Physiological and Therapeutic Working of Poisons	.....	Dr. von Basch.	
	Instruction on Post-Mortems	.....	Dr. Weichselbaum.	
	On Exudation and Blood-Tumors in the Female Pelvis	1	Dr. Schlesinger.	
	Operative Surgery on Cadaver	.....	Prof. Weinlechner.	
	Surgical Operations and Bandages	.....	Prof. Böhm.	
	Surgery and Diagnosis of Women's Diseases	.....	" "	
	Different Methods of Bloodless Operations	1	Dr. Neudörfer.	
	Treatment of Joint and Spinal Deformities	2	" "	
	Anatomy and Surgery of Genito-Urinary System	.....	Dr. Jurié.	
	Practical Obstetric Operations	5	*Dr. Rokitansky.*	
	State and Domestic Hygiene	5	Prof. Nowak.	
	Senile Changes in the Eye	4	Dr. Feuer.	
	Refraction and Accommodation	6	" "	
	Operative Gynæcology on Cadaver	.....	Dr. Lott.	
	Diseases of Spinal Cord and Peripheral Nerves	6	Dr. N. Weiss.	

By consulting the bulletin-boards at the gates of the hospital and elsewhere on its walls, each change of instructor or formation of new courses can be found, usually a week ahead, though some of the courses are gotten up by a club, or set of students who engage a teacher in advance and admit none but a member of their coterie. The latter courses are never posted, and one must depend on his own or his friends' exertions to obtain advantages of this description.

Let us now give a casual glance at the different general subjects, taking up, first,

Anatomy.—The death-rate, twelve to sixteen daily, supplies material for dissec-

* Omitted in the schedule of the lectures and courses of the University of Vienna.
† Omitted altogether in the catalogue.

tion, and the privilege is not expensive, but unless the student has ample time there or looks forward to establishing himself where he may have few opportunities for anatomical studies, he had better not devote himself to a branch that can be followed at home, where so many of the practical courses are unavailable. The fact, too, that bodies or portions are so easily gotten breeds among some men a careless hacking propensity that does not result in that knowledge acquired where subjects are harder to obtain and more expensive.

The same remarks will apply to normal histology, which should be learned before leaving home, as the individual, and not the class, is the worker in this field. Surgical anatomy is given with the operative course.

Physiology.—The writer is unable to state facts in this department, though Leipsic seems the greater favorite with men taking this specialty.

Pathology has some great masters in Vienna and not a few disciples. One of the most profitable microscopic courses is an hour and a half in the middle of the day, when the results of all the last twenty-four hours' post-mortems are discoursed on and shown, while, at the conclusion, three men, appointed each day, examine under direction the head, chest, and abdomen of an unfortunate, reserved from the skilful hand of the demonstrator for the ambitious scalpel of the student. Through the kindness of the gentleman in charge I obtained quite a number of specimens, which may be mounted at leisure, but I fear they will not be as satisfactory as if I then had had time to devote to this mechanical part of microscopy.

Internal, or what we call the practice of medicine, receives treatment from such able hands as Professors Bamberger and Duchek, etc., while almost each organ claims the attention of men who in some cases have done as much for making the organ conspicuous as its consideration has rendered them famous. In some of the courses of the students each pair has a case to consult over, theoretically treat, and, in case of death, follow to the autopsy-room to verify the criticism of the teacher, thus made doubly careful in expressing his opinion.

Professors Billroth and Dumreicher are the worthy exponents of surgery, and no man can enter the former's clinic without being impressed with that great surgeon's manner. The trouble is that he is so popular that his small operating-room does not admit all of his admirers, while his lectures are delivered in so modest a key that only a favored few can hear them, and so great is the number of assistants that vision, essential to appreciating fine work, is interfered with. The cases that one does see point with emphasis to the magnitude of the study. The perfect coolness of the operator tells eloquently the timid man that with common sense, experience, and study almost anything is possible to one who believes enough in himself to be cool and resolute. The moral force imparted by such a master is worth many an hour spent in stretching one's neck over a classmate's shoulder.

On alternate days the class accompany the professors through the wards and catch a glimpse of that after-treatment which is as essential as the operation to success. By remaining after the hour one often sees cases undisturbed, or may attend the dirty crowd of Jews and Gentiles that come to this surgical Elisha, in many cases to be reminded of Abana and Pharpar, rivers of Samaria, if the Danube, the water of Viennese Israel, should fail to cleanse.

Courses on bandaging, fractures, orthopraxy, operations on almost each organ, besides general surgery on the cadaver, make Vienna no second-rate place for the study of this department, but it must yield to London in the number and weight of surgical reputations, though by the concentration of work it is superior to the latter place, and one has the possibility of learning far more than the potentiality of retaining.

In selecting teachers in this and every other branch, do not avoid popular men, but large classes, for each new entry subdivides the attention due you until it becomes almost a minus quantity, and you are slighted to make room for the ubiquitous "one more."

The number of courses affords ample opportunity to review a subject, while the amount of material secures familiarity with all operations.

One of the disadvantages of Vienna, compared to London, is that only the regular assistants of the professors have the dressing and bandaging of hospital patients, while in the London Hospital, famous for its acute cases, a man may be-

come a dresser for three months at a time, supplemented by a week's residence each month in the hospital, on the payment of a moderate charge.

Nothing can equal this face-to-face acquaintance with cases and responsibility enough to emphasize the salient points.

The Ear.—The average student or nascent doctor has an idea that the ear is rather an excrescence than an organ, too insignificant or too intricate to merit attention beyond that well-balanced point necessary to a diploma; nor does one fully realize its importance until he has heard some aural specialist dilate on the subject.

A few lectures of Professor Gruber or Politzer, or a course with their rapid-speaking assistant, Dr. Pollak, will soon convince the ignorant that a deaf man is in outer darkness. Here let me just mention that the would-be medical Alexander must not be discouraged because he despairs of ever reaching the perfection that each specialist enforces as the only thing worth living for. Some go farther and assert in manner and doctrine that perfection is attainable only *via* a true knowledge of the eye, skin, uterus, or pathology. It is a great comfort, when overcome by the enormity of one's own ignorance, to whisper a quasi-consolation and say, perhaps outside of these specialties these professional Pharisees are as other men.

The eye, in Vienna, receives the attention it merits from such leaders as Professors Arlt, Stellwag von Carion, Jaeger, together with a number of assistants, whose courses cover the whole ground of eye-surgery. In fact, there seem to be too many subdivisions. Thus, one man takes up the diseases of the anterior part of the eye, a second pushes on to the fundus with the ophthalmoscope, while still another gives operations with practice on the eyes of animals and the dead face. It is true each teaches a good deal, but I see no reason for such multiplication, involving extra payments, when at least two of them might consolidate. By taking courses with different assistants one has a chance at the whole repertory of the eye-wards,—an inducement that many seize.

Obstetrics.—There are about ten thousand infants born in the Vienna Hospital per annum, giving three thousand to each ward. Nine thousand are illegitimate; in fact, the offspring of married parents are said to present almost always transversely.

It is a laughable sight to see, on reception evening, a long train of thirty or forty pregnant women sailing like a fleet of Dutch luggers into the examining-room. Here each one is explored by the assistant, discussed *pro re nata*, and, if not near full term, dismissed for a more convenient season. The rest are received, and not a few may be delivered that night. In these receptions the students belonging to the class can all make external examination, a point much more insisted on in Europe than in America, and a few may, after the assistant, verify his diagnosis by internal touch.

Professors Carl Braun and Joseph Spaeth deliver clinics each day, and men who join their classes have the privilege of the receptions and obstetric wards.

Here a knowledge of the ropes will not be amiss to one desiring cases.

Each class is subdivided into sections of four or five, and two of these sections come on every twenty-four hours. A schedule is made out each week, so a man may make his arrangements for his night- or day-watch in advance. Should any of the section appointed for the night fail to put in his card before four in the afternoon, the men who by nine that morning have placed their names on a list provided will be chosen as substitutes for the absent parties. Thus the obstetric owl is often rewarded for his industry by a series of night-watches limited only by his appetite and perseverance.

After one has thus secured his position in the ward, it is his next business to get a case, and when he has signed his name on a blackboard at the patient's head he cannot interfere with, or be disturbed by, others until he relinquishes the case or delivers the child. Complications arouse the assistant unless the attending student is known to have had some experience. Those who join both Braun's and Spaeth's clinics may come on regularly at least once a week, while they may substitute whenever they please. By politeness to the midwives, who are almost all graduates of that department (Prof. Gustav Braun delivering lectures exclusively to them in the third above-mentioned ward), and courtesy with the assistants, all of whom I found to be gentlemen, the student can gain as much obstetric knowledge in Vienna as in Prague or Dublin if he really work.

At one ward there is no reception each day, the other two alternating with it day and night. The day reception is preferred, because one can often tell by 10 P.M. if he will get a case, the liability continuing until daylight in night receptions. It is often a pure matter of luck. Sometimes twenty cases may be born in twelve hours; at others the snoring women alone break on the monotony of the watch.

The babies when born are soon put into a blanket, and a child risks losing its identity with half a dozen others on the same table in different stages of dressing. On Fridays the priest baptizes the result of a week's labor, the nurses finally taking up armfuls of these living sticks to be distributed again to their parents. The "touch-courses," which are given by assistants, are excellent, as one may learn, in twenty-five or fifty lessons, a great deal about the abdomen, cervix, vagina, as well as the positions of the child in the pregnant woman.

They are comparatively very expensive, averaging a half-dollar an hour; but, as there are only three men in a class, there may be some excuse. The best teachers are always in demand, and it is well to see one of them upon arrival, as they make out their lists some time in advance. This rule applies with equal force to gynæcology, as the writer can unfortunately testify.

Few courses humiliate a beginner more than obstetric operations on the cadaver, and few are so satisfactory. The books, so glib about the application of forceps, the simplicity of turning, dwell rightly on the horror of craniotomy, but mere black and white does not impress one with the difficulties in the same way as an endeavor, before a watchful instructor and criticising class, to deliver the dead woman, *per vias naturales*, of one of the numerous still-born children that are thus utilized. The man who takes two courses at least on this important topic from different assistants will glean a variety of opinions as well as experience that he will never regret. One thing, however, it is to be hoped he will never attain, and that is the alacrity with which students and instructors leave the dead house for the lying-in-room to make examinations with hands imbrued with the blood of the dead, and it may be consciences dyed with the blood of the living. I cannot but think that the awful inroads of puerperal fever, and the numerous deaths thereby, arise largely from this criminality in attempting to satisfy the meagre sentiment that foreigners generally have for women by a paltry wash of carbolized water after post-mortems on even puerperal subjects.

It requires more than a basinful of the "multitudinous seas incarnadine" with permanganate of potassium to rub out the "damned spot" so acquired, and God knows Americans had better stay at home than learn abroad to carry under the badge of their healing office desolation to the hearth of a confiding family. Much as I respect these Viennese teachers for their attainments and the good they have done in advancing obstetrical science, I cannot help looking on them as guilty of something near homicide while they permit or advance such criminality. It is not for the students to prevent it; the instructors alone have the power; only let the American in Vienna remember it as a light on a hidden rock, not a guide, but a signal of an impending calamity. The profession here and elsewhere will not do its whole duty to its neighbor until obstetricians refuse contagious cases which may endanger mother and child.

Diseases of Children.—There are numerous lecturers on this subject, but the favorites are Professor Monti, at the Polyclinic, who, besides being a thoroughly practical man, is an Italian, with a knowledge of German that foreigners can sympathize with and understand. The other is Professor Wiederhoper, who lectures at St. Anna's Children's Hospital on diseases that are more severe than a peripatetic clinic allows. As these two lecturers have consecutive hours, one may take both at a time. Before taking up the material a half-hour is spent most advantageously on a regular system of lectures. Once a week children's surgery is treated, making a pleasant variety in the usual *menu* of colic, crusta lactea, etc.

Venereal Diseases.—Whether the large standing army, that Austria finds is a producer as well as a consumer, is the cause of so much syphilis and so many children, I cannot say, but the number of men and women that one sees in the wards of Hebra, Sigmund, Kaposi, Zeissl, Neumann, etc., suffering with what chivalrous negroes call "ladies' fever," is astonishing. One

would think that the special pathology of this hydra-headed disease would be exhausted by such observers; but as it still baffles old heads the young ones are allowed a fair turn at the problem, and the lectures in this department are interesting and practical. In a single lecture I have seen as many as twenty patients with different types or stages of syphilis arranged in regular gradation to illustrate the question under discussion. The women in one department vie with the men in the other in illuminating the subject.

One cannot but feel disgusted, however, when he sees the unfortunate women who are sitting around a table, at a signal from one of the she-bears that mount guard, or from the hardly less brutal assistant, compelled to hurry off the little covering to their nakedness, and reveal, as a text to a serio-comic lecture, parts that even in the most debased women deserve the respect that nature entails on animals. I do not say that this is the universal procedure, but in one of the courses I was much tempted to instruct the instructor on points of ethics by a more forcible and striking way than mere precept.

This is a matter the students *can* ameliorate, for if, instead of smiling at dirty jokes, or passively sitting at the feet of a filthy syphilitic Gamaliel, they firmly discountenance such bullying, by, in a manner most effective with teachers yearning for American patronage, withdrawing their subscriptions until he finds why he is obnoxious, his purse will teach him what his gilt-edged conscience has forgotten, and Americans would be there as they are at home,—the men most manly to women in the world.

Skin Diseases.—For diseases of the skin, exclusive of syphilis, Vienna offers every opportunity that a corps of unsurpassed teachers and material from all the surrounding provinces afford. The parasitic diseases are especially well represented, as the filth and squalor of some of the cities' inhabitants, but more so of the peasants in the vicinity, make a paradise for vermin that is not wholly detrimental to the dermatologist.

Nervous Diseases.—In regard to diseases of the nervous system, and the didactic lectures on medical topics, I can, unfortunately, say nothing from experience. My impression, however, is that one should use Vienna as a field for the *practice* of theoretical medicine learned before starting, with such valuable amendments as the instructors give in each course.

The cost of a six weeks' course ranges from five to ten dollars. In some the home student pays only one-half of the amount charged a foreigner, a species of protection justifiable only when one thinks that the average American can get just twice as much out of his advantages.

Do not let your patriotism open your arms to every fellow-countryman, for the same caution is required there in choosing friends as is necessary on this side of the Atlantic, and you will find that salt water does not wash out all the snobbishness and low breeding of men, any more than it makes an unaffected American forget his native tongue in a year, as I have heard some students affirm, pleading a trip abroad in excuse for assaults on their mother-tongue, quite forgetting the more piercing horn of the dilemma,—*i.e.*, could they ever speak English correctly in America?

Above all things, do not come home with the faith in those who stayed there that they will believe your claims to a personal acquaintance with the various intellectual giants. It is rather amusing to hear one boast of an intimate friendship with a great gun, and know by experience how little notice is taken of students by their superiors. I myself was once ambitious, and having accosted a very Goliath with a smooth stone I had found pleasing to Germans at large,—*i.e.*, "You speak English, do you not, sir?"—I received the answer in almost a Yankee twang, "Yes; but I have no time to speak anything now." From that time my vaulting ambition was hobbled, at least in that direction, and my friends are not bored with my dining with Herr Professor Ritter Von etc., or my smokes and beers with the Kaiserlich Königlich Allgemeine Doctoren.

So much for the student of medicine. Now, since "a man's a man for a' that," it will not be out of place to say that in no European city can better amusement be found than in Vienna. The Vienna Opera, at a ridiculously low price, offers the best music and effects in the world. The concerts of Strauss and at the public gardens, coupled with the numerous excellent theatres, afford relaxation that is beneficial in more ways than one. The city is healthy, has a delightful water-supply, living is

cheaper than in New York, the climate, though cold in winter, has plenty of sunshine, and, taking it all in all, I know of no European city that is more agreeable. An English church, where Americans are always welcome and some most efficient in the music, renders it possible (a chance, I regret to say, that all Americans do not accept) to hear our beautiful service in our own tongue, a privilege much enjoyed by the married men; for, independent of its religious influence, Sunday was a day when we could be like other men, and have a little home-life even at that distance from our native land.

To men who think of marrying before going to Vienna, I would ask them to remember how much they must leave their wives, if they intend to study, and that too in a place where ladies have not the privilege of walking or shopping unattended, as with us. If, in spite of all the disagreeable prospects that hem in a doctor's wife in Vienna, she choose to accept the situation, and, with the ingenuity that true women can show in making time pleasing and profitable, she says, "Thy people shall be my people," then by all means marry before leaving home; only it is fair that she who is to be the partner of your life shall know that in Vienna ladies are denied many of the ways of enjoyment that are permissible with us.

Besides a wife, you will find her a protection against many of the temptations that ruin young Americans abroad, and will have reason to look back on your mutual dependence as one of the most pleasing features of a pleasant era. One remark before closing,—the relative value of a year's trip abroad compared to a year's life as a resident in a general hospital. I do not think they admit of comparison, for both are unique. Of the two, by far the more profitable, I should say, was the hospital residence, but by the combination the good qualities of both are intensified. Regretting that this paper is so necessarily egotistical, but assuring you that in such an article of personal experience the individual must appear, I offer it in the hope that it may benefit those who, like the writer, desired some hints before making Europe a temporary home.

THE *Chemische Zeitung* reports that considerable quantities of arsenic have been found on the examination of green carpets at Bonn.

"WHISKY AS AN ANTISEPTIC DRESSING."

BY J. L. SUESSEROTT, M.D.

MR. EDITOR,—In September, 1874, I contributed an article with the above caption for your journal, which can be found on page 774, vol. iv., and in which I refer to the use of whisky having been suggested by Dr. D. Blair in the *Glasgow Medical Journal* for February, 1870. I trust you will pardon my persistence in recommending an article which, if we are to judge by the absence of favorable or unfavorable reports of its use in hospital practice or by individuals through the medical journals, has not received the endorsement of the profession; but my surprise at the want of appreciation of one of the most pleasant, in application, of all remedies in use has frequently been excited, and I cannot refrain from referring to a casual claim of the benefit of *alcohol* in a case reported in your last issue. Although the writer of the article does not give any more importance to the "alcoholic lotion" than he does to the carbolic acid which was combined with it, and which, in my opinion, was entirely superfluous, I desire again to urge upon the readers of this journal, which has given me so many valuable hints, the propriety of submitting to a fair and impartial test an article that will render the use of the more recently discovered, and in many cases offensive, antiseptics almost entirely unnecessary.

And, lest they may fear an undue stimulating or irritating effect, let me say that *undiluted whisky* is found, by nearly all patients, a very grateful vaginal wash in leucorrhœa even where there are uterine fissures and ulcerations. But to the article above alluded to, reporting a case of hospital gangrene, on page 104, No. 339, vol. xi. of this journal. And whilst I disclaim any desire to criticise the treatment other than to regret the delay in using alcohol, I will venture the assertion that if it had been freely used, as recommended in my contribution to vol. iv., the attempt to save the foot would not have been abortive.

The article of Dr. Pooley has been so recently in the hands of your readers that I need quote very little of it; but there is one paragraph that I wish especially to

refer to. After the doctor was compelled to resort to amputation and the most approved treatment had been used, the disease—gangrene—reasserted itself in its most violent form. I will here use his own words, italicizing those that I desire to be especially noticed: "The gangrene continued for several days, the exudation appearing to increase in density, and numerous sloughs of connective tissue came away. The skin remained uncomplicated throughout. *A strong alcoholic lotion*, with carbolic acid, *was now ordered, and almost at once a change for the better was discoverable; healthy granulations began to spring up; the remaining sloughs were cast off, and in a week we were able to begin to close the stump with adhesive straps*, and it healed very rapidly, together with which the general health of the patient improved so that in three weeks he was able to go out."

As my former article, which by the use of large quotations from Dr. Blair was made as comprehensive as my feeble ability was possible to accomplish, is accessible to all of your readers, I will not further trespass on your space, but will only say that a decade of years, through which I have used the article in question very many times, has not in the least abated my admiration for and confidence in it. Within this month I treated a pulpified wound on the top of the head of a man of over forty years of age, which at first presented the most unfavorable appearance, as it had been inflicted by a blow with an axe-handle in the hands of a strong young man, with no other dressing than whisky, and as a result had the parts to heal without any suppuration, sloughing, or the least tendency to erysipelas. The injury was inflicted on election-day, November 2, and its severity upon the nervous centres was so great that, notwithstanding the entire repair of the scalp, at this writing, November 25, the entire right side of the patient is very much benumbed, and untoward brain-troubles may yet be encountered.

In conclusion, permit me to suggest that if any one should fear that whisky or its congener, alcohol, does not afford a sufficient antagonism to septic influences, let them be applied upon carbolated cotton, —an article of comparatively recent manufacture, and very convenient.

CHAMBERSBURG, PA.

TREATMENT OF DIPHTHERIA.

BY G. HAYWARD COBURN, M.D.,

Grand Falls, New Brunswick.

HAVING during the last three years had considerable opportunity of observing and treating cases of diphtheria, and having in that period tested many of the numerous methods of treatment which have been published in our magazines, I at last settled down to the line of practice to be detailed, it having afforded the best results of any I have tried or know of.

I prescribe—and it will strike the reader as nothing new—tinct. ferri chlor. with potass. chlor. Doubtless thousands of physicians use the same drugs, but, as far as my knowledge extends, comparatively few give as large a dose and with as great frequency, which supposition is my only reason for writing this paper. I give to a child twelve years of age the following:

℞ Potass. chlor., ʒi;
Tr. ferri chlor., fʒss;
Glycerin., fʒj;
Aq. q. s. ad fʒiij.—M.

S.—A teaspoonful in water *every half-hour.*

It will be seen that ten minims of the iron and three grains of the chlorate are given every half-hour, making in twenty-four hours one ounce of iron and two drachms of chlorate of potassium.

In these large and frequent doses I am persuaded lies the secret of success. I have time and time again been called early to a case of diphtheria, finding one or both tonsils distinctly covered with false membrane, temperature 101° F. to 103° F., pulse 90 to 110, etc., prescribed the above, and been surprised next day to find the membrane either gone or reduced to a mere film, with no tendency to extend; the temperature reduced to 99° F., or even normal. Of course such a result cannot be looked for in every case or even in a majority of the cases, although it is by no means uncommon in patients seen early. Still, I think that in any case such a mode of treatment gives the best chance of successfully warring against grave constitutional and local symptoms, and of promoting speedy convalescence. The first few doses often cause vomiting, but this soon ceases, and the stomach bears it well. I am in the habit, if the symptoms assume a favorable type, of lessening the frequency with which the

dose is given after the first twenty-four hours, at first to every hour, and so on. Of course this is not the only treatment, though it is the sheet-anchor: *locally* I usually confine myself to a 1 to 20 solution of carbolic acid thrown on the affected parts by means of an atomizer with a long nozzle, and sometimes used as a gargle. *I never use swabs*, believing that the rough removal of the false membrane which they are apt to cause gives too good a chance for septic poisoning.

Swelling of the glands, if great, is treated by the application of ice; if not, any warm application does nicely. I think I have seen the old-fashioned application of a strip of salt pork do good. The system must be supported by nutritious liquid diet, broths, beef-essences, milk, etc. Stimulants, I think, are not usually needed at first; during the latter stages they are often useful, and, indeed, demanded, brandy being the best form. Of course, symptoms must be treated as they arise, and no routine ought to be laid down, but, I repeat, the sheet-anchor is to be found in tincture of the chloride of iron with chlorate of potassium in large and frequently-repeated doses.

A REMEDY AGAINST DUPLICATING PRESCRIPTIONS.

BY E. T. BLACKWELL, M.D.

THE use of a prescription, after it has fulfilled its temporary mission, by any unauthorized person, which includes the one to whom it was issued, is a great evil. It fosters a habit of self-medicating, on the part of a sick person, or one who fancies himself such, which induces him to rely on his own opinion in medical questions, wherein the physician is the only competent judge. Moreover, it tends to establish the empirical use of a remedy which is foreign to the design of its author. Under the present system prescriptions are not only refilled for the same patients, but are lent to neighbors and friends, in view of fancied resemblances in their complaints. A sort of proprietorship is thus established, and a remedy, devised in strict integrity, goes upon a journey of empiricism and misapplication.

A great injury, therefore, happens, not alone to the deluded ones who ignorantly and disadvantageously use the medicine, but also to the physician who has devoted his fortune, his time, and his exertions in preparation for the right understanding of diseases and the intelligent application of remedies for their cure. A prescription, wrested from its appropriate use, becomes a competitor to the person who issues it, and may defeat his aims in the practice of his profession. While his gains are diminished, his self-respect is wounded, in view of the unlearned in medicine discussing the appropriateness of his combinations in this or that disorder.

A prescription, issued some years since by the writer, was declared to be a good one by the patient, who further endorsed it, saying it had been refilled thirteen times. One made by a distinguished Philadelphia professor, some time deceased, is so highly esteemed that it has had an extensive circulation in a district not remote, and is still in full use.

This is a grievous wrong, against which only the amplest co-operation can be successfully brought to bear; and this should be exerted upon our national legislature, to the end that prescriptions, uttered in manuscript, be protected by copyright, the handwriting of the author and his autograph being held sufficient to establish his claim to the property in question. A patient should no more be permitted to multiply copies of a prescription, or duplicate the medicine it calls for, than he should a book or magazine that he buys.

Let us, therefore, no longer tamely submit to this infraction of our rights, but vigorously assert our claims, continuing the agitation until we obtain the justice so long denied to our patient and suffering profession.

NOTES OF HOSPITAL PRACTICE.

LOUISVILLE HOSPITAL COLLEGE OF MEDICINE.

CLINICAL SERVICE OF DUDLEY S. REYNOLDS, M.D., PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE HOSPITAL COLLEGE OF MEDICINE.

Reported by A. H. KELCH, M.D., Stenographer.

ON THE EYE.

CASE I.—Michael F. has been here before with the disease tinea tarsi. He has been an occasional sufferer for many years, and has for a long time had this peculiar disease of the lash or the hair-

follicles,—a parasitic disease, which manifests a special preference for two classes of people: one class who live in a bad atmosphere and suffer from constitutional debility, and another who have a general tendency to lymphatic obstruction,—the so-called strumous diathesis. He has an obstruction in the Meibomian ducts. Sometimes obstructions in the orifices of these ducts become very troublesome from the fact that the occluding material is transformed into a semi-cartilaginous substance, which, if permitted to remain, is transformed into carbonate of lime, developing a real chalk-stone.

Carbonate of lime in the Meibomian ducts is by no means an uncommon occurrence. A patient, who came to my office a few months ago, suffered from the friction of the rough surfaces of the lids, and thought he had some foreign body lodged beneath. Careful examination revealed that the ducts of the Meibomian glands were obstructed. They were distended, and these bodies projected at the fine border of the lid; the little points had become very irritating. Laying open the ducts in a longitudinal direction, these collections were easily turned out. If the duct were cut transversely, the cicatricial tissue resulting from the separation of the wound would close the duct permanently, thus augmenting the difficulty which now exists, inasmuch as it simply creates a permanent obstruction.

In the case of Mr. F. I shall open these ducts with Beers's knife.

I find them filled up with chalky matter, which comes out in little particles, as you see them here on my knife; the particles are small, but numerous. The reason why these are obstructed in this case is because the patient has lost a considerable portion of the lining of the lids, from long-continued inflammation, and, I was about to say, caustic applications, and the cicatrices have closed the orifices of the ducts along the free border of the lid.

The existence of parasites in the hair-follicles which transmit the eyelash gives sufficient irritation to keep up the redness and swelling, which you observe is considerable.

To relieve this condition it is not alone necessary to pursue a course of local treatment, but it is necessary to treat the constitutional debility which predisposed to the development of the parasite. An ointment composed of calomel in almost any strength—the yellow oxide of mercury, because it is an amorphous salt and can be more evenly diffused throughout the excipient—is perhaps preferable. The red oxide of mercury is a crystalline substance, and from this fact its action may be too much centred in one point. The yellow oxide is not open to this objection. It has been claimed by some that there is no difference between the red and the yellow oxide. But if you will take the trouble to perform the experiment of adding the yellow oxide of mercury to a saturated solution of oxalic acid, you will find a precipitate of white oxalate of mercury readily and quickly thrown down, while such precipitate does not so readily fall from the addition of the red oxide. We will give Mr. F. the yellow oxide of mercury in the proportion of ten grains to the half-ounce of vaseline. A wash shall be given him to aid in the solution of crusts in the lash. The best thing for this purpose is the bicarbonate of soda, and next to that, perhaps, the sulphite of soda. We will give him forty grains of sodæ bicarb. to the ounce of water, which must be used to bathe his eyes, and after that let him rub in the ointment of the yellow oxide. If he should apply the ointment without previously removing the crusts, it would remain on the surface of the scab and do no possible good.

Case II.—P. B., æt. 57. The most perfect specimen of jaundice I have seen in a long time, and he has cataract in both eyes. Upon examination I find the perception of light and shadows here is sufficiently delicate to warrant the conclusion that he is a favorable subject for operation. But before he is operated upon he must receive constitutional treatment. I will therefore give him sulphate of quinia, ℥i, divided into twelve powders, one to be taken after each meal, and elixir of lactopeptin, ℥iv, a teaspoonful of which he may take before meals.

It is bad practice to operate for cataract by extraction, or, in fact, to do any kind of an operation, upon a person whose general health is so evidently bad as is this man's. He is moderately well nourished; his tongue is tolerably clean; he says he has a fair appetite, sleeps well, feels weak, but he is at this time in as good health as he has been during the last six or seven years. His wife says that his skin has been as yellow for four years as you now see it. His

pulse and respirations seem normal, but I am unwilling to operate upon him until after he has been brought fully under the influence of quinine. He is to return here next Monday, when, if his general condition appears good and the weather is not unfavorable, I shall extract the cataract from one eye, and when that has been entirely restored and is no longer in the least degree irritated from the effects of the operation or other cause, and if the patient should desire it, I shall proceed to extract the cataract from the other eye.

It is not safe to undertake the extraction from both eyes at the same sitting, as in the case of this man, where the general health is evidently not good, the man being jaundiced, if I were to extract the cataract from both eyes, sloughing of the cornea might ensue, or suppurative inflammation of the uveal tract might occur, and in either case both eyes be lost; whereas if one eye only be operated upon at a time, and such an unfortunate occurrence as I have just named should overtake the patient, he has still a chance, after he has regained his general health, to have a successful operation performed upon the other eye.

Case III.—Mrs. G., you all remember, came here a week ago from Elizabethtown with a lachrymal fistula in the left cheek. It had been discharging muco-purulent material for eight months. She first noticed the swelling near the inner corner of the eye, just at the point where the lower lid joins the nose. This swelling grew worse, was painful, and caused the lids to be closed for a number of days. Poultices were employed until the abscess pointed externally and finally ruptured, discharging its contents upon the cheek, leaving a frightful-looking opening, with its inflamed margins and offensive contents as you all saw it a week ago. You may remember that last Monday I nicked the punctum in the lower lid with a pair of fine scissors, and then introduced what is known as Weber's knife,—a curved probe-pointed instrument, having the cutting surface upon the concave edge of the blade. Passing this instrument through the enlarged punctum and carrying it into the tear-sac, the handle was swept from a temporo-frontal position over towards the nose, until division of the inferior canaliculus was extended quite up to the internal commissure of the lids. You may remember that as soon as this section of the inferior canaliculus was made there was an escape of a considerable quantity of pus, both from the opening made by the knife and from the fistulous opening upon the cheek.

An Anel's syringe, loaded with a five-minim solution of carbolic acid to the ounce of water, was employed to wash out the tear-sac. Immediately after this a No. 6 Bowman's probe was with some difficulty passed on through the nasal duct. The probe encountered a pretty firm stricture occupying about one-fourth of an inch of the upper extremity of the nasal duct. By gentle pressure and a little coaxing the instrument finally passed by dilating the contracted canal. I thought at first it might become necessary to cut out this callous tissue upon the cheek and close the fistula with silkworm gut suture, which is much less irritating than any other substance, not excepting silver wire; besides, it is much finer than wire, more flexible, and therefore better suited to the purpose. To my surprise and the patient's delight, the cleansing of the tear-sac practised a week ago, and the daily introduction of the No. 6 probe, have been followed by the closure of the fistula and the entire disappearance of all morbid matters from the tear-passage, and the patient, as you see, is now substantially cured. The discoloration is disappearing from the cheek, the point where the skin was perforated is already depressed, and will eventually leave a depressed white cicatricial line to mark the site of what you will all bear testimony was a very ugly fistulous opening.

To insure the potency of the strictured part of the nasal duct, I shall now introduce a Bowman's probe No. 4, which you see passes with great ease, meeting with no obstruction whatever. I choose this probe because for two days no probe has been passed, and it was reasonable to suppose the canal was scarcely so large as it was when the probe was being introduced daily.

Case IV.—Miss Edie G., æt. 15, a school-girl, came here last Monday, as you remember, suffering from asthenopia, which means that the eyes were tired,—ached on attempting to read, and on continuing for a few moments they became quite painful, so much so she was obliged to desist. She claims to have perfect sight, and complains simply of her inability to continue the exercise of that perfect vision. This is evidently due to an excessive strain upon the

accommodative apparatus of the eye, in order to make up the defect of refraction, the exact nature of which can be determined only after complete suspension of the accommodation. To accomplish this a solution of sulphate of atropia in the proportion of four grains to the ounce of water was ordered last Monday. She was instructed to put one drop of this solution into each eye every morning and evening, and she has come here to-day for the purpose of having her refraction tested. With a sheet of Snellen's test letters placed at twenty feet from the patient, she is unable to recognize that there are any letters upon the paper. With Donders's stereopæic disk we find that in the vertical meridian of the right eye $V = \frac{20}{CC}$. In the horizontal meridian she does not see so well as without the disk. A convex lens with a refracting power of $\frac{1}{10}$ enables her to read $\frac{25}{LXX}$ in the vertical meridian. She is unable to decide, as you observe, which glass, $+\frac{1}{6}$ or $+\frac{1}{7}$, gives her the clearest vision in the horizontal meridian. Reversing the disk and bringing the slit in the vertical meridian, we find her able to see as well with $+\frac{1}{6}$ as with $+\frac{1}{10}$, and she makes no choice of any of the intermediate grades. Therefore we conclude that her accommodation is still active, that it is not yet suspended, although she has continued to use the four-grain solution of atropia faithfully for the whole week. Dr. Schell, of Philadelphia, has lately brought to the notice of the profession, in the *Philadelphia Medical Times*, a new drug called "homatropine," which he claims will fully suspend the accommodation in thirty minutes, and that the effects pass off within thirty-six hours. I have sent for some of this new drug, and shall consider the profession and the general public much indebted to Dr. Schell if I shall be able to confirm the results which he claims to have obtained. The patient must continue the use of the atropia and return to the next clinic, when we shall continue the test until the exact state of her defective refraction has been ascertained; then we shall proceed to correct it with the proper glasses.

(To be continued.)

Dr. T. J. Thomason died recently at Perrineville, New Jersey, from cancer of the tongue. In 1873–74 he was president of the New Jersey State Medical Society.

TRANSLATIONS.

On the Cure of Bright's Disease.—Prof. E. de Renzi, of Genoa (*Virchow's Archiv*, Bd. lxxx. p. 510), has within the past two or three years had a number of cases of Bright's disease under his care. In six of these it was possible to keep accurate notes of the quantity of urine, albumen, and the other principal symptoms, and at the same time to observe the effects of the various remedies used. For a certain number of days a given remedy was employed; then for another series of days another means of treatment was employed. Thus by a comparative method the influence of various methods of treatment could be studied. Some of the remedies were quite new, which lent additional interest to the investigation. Such a study would appear all the more necessary, because the usual treatment for Bright's disease, although often of use in improving the patient's condition and appearing to arrest the course of the disease, is in most cases quite ineffectual in bringing about an entire cure. The conclusions drawn by Renzi are as follows. 1. Chronic Bright's disease left untreated shows no improvement, and must be excluded from the category of diseases which occasionally terminate favorably without treatment. During the first days of treatment in the clinic, or when the treatment is suddenly broken off, the quantity of albumen in the urine is increased. 2. *Fuchsine*, which has been recently brought forward as a remedy in Bright's disease, causes a marked diminution in the quantity of albumen. Renzi has used it under two forms, dissolved in water, or mixed with an indifferent extract in pills of two and a half centigrammes. On account of the fact that the deep coloration of solution of fuchsine prejudices patients against it, the pill-form appears to be the most convenient. 3. The daily dose of fuchsine may be made much larger than that heretofore prescribed. Renzi usually begins with a small dose, as 0.05, gradually increased to 0.25 within twenty-four hours. He has never observed any untoward physiological effect from the use of fuchsine. Depending upon the dose of fuchsine the urine begins sooner or later to assume a red color, which it retains during the continuation of the treatment, and usually for five days after. 4. In Bright's disease the urine often shows mucus; fuch-

sine is particularly useful in combating this condition, which it removes entirely. The mucous membrane of the digestive organs becomes deeply colored by fuchsine, and the plasma of the blood also becomes decidedly colored. Investigation shows this latter effect to be due not to any increase in hæmoglobin, but to the solution of fuchsine in the blood. 5. If fuchsine does not appear in the urine, this is a sign of an organic disturbance; in this case it is of no use against the albuminuria. 6. Rest in bed is a valuable adjunct to treatment in Bright's disease, for the purpose of limiting the amount of albumen passed. In connection with milk diet this plan caused the most considerable diminution of albumen. Renzi has often observed that unusual movements of the patient have an unfavorable tendency on the course of the disease. 7. Apomorphia is usually well borne, and Renzi has used it in doses of five to six centigrammes without disagreeable effect. In one case this method alone served to improve materially the patient's condition.

Cure of Strabismus by Mydriatics.—Dr. Boucheron read a paper on this subject recently before the *Académie de Médecine* (*Le Progrès Méd.*, 1880, p. 562). His treatment is based on the physiological fact, not previously published, that the accommodation of the eyes for short distances governs the convergence of the eyes. Dr. Boucheron proposes to combat the excessive convergence of hypermetropic eyes and the converging strabismus resulting therefrom by suppressing the accommodation temporarily by atropinic paralysis of the muscles of accommodation. The results of this treatment may be summarized as follows. The condition *sine qua non* of success is the intermittence of deviation of the strabismus, indicating that the internal recti muscles are no longer retracted and shortened as a result of their habitual vicious position. Instillations of sulphate of atropia (one and a half grains to the ounce of distilled water) should be made from the first appearance of the strabismus, before any change takes place in the convergent muscles. The instillation should be practised in both eyes, so as to obtain a complete paralysis of the muscles of accommodation. One or two drops morning and evening of the solution above indicated produce the pupillary dilatation desired. The instillation should be continued during a period sufficiently long to cause this habit of excessive convergence when the infant looks at any near object to disappear. This medication places the child suffering from hypermetropic strabismus in the condition of non-strabismic hypermetropic persons. The duration of the treatment is less long when the child is younger and the strabismus of relatively shorter standing. Generally the strabismus disappears within two or three weeks, but it shows a tendency to relapse for some months, or even a year, subsequently, in older children. In the cases under Dr. Boucheron's care the atropia has caused no inconvenience. When atropia is badly borne, one of the other mydriatics, as duboisine, may be employed in place of it. In certain cases, myotics, like eserine, which immobilize accommodation by contracting the ciliary muscle, may modify the relation which exists between accommodation and convergence and cause the strabismus to cease; but mydriatics have the most certain effects. Employed in nine cases of intermittent convergent strabismus in children, this plan of treatment has been successful eight times.

Carbolic Acid as an Antipyretic.—Dr. Desplats (*La France Méd.*, 1880, p. 579) asserts: 1. That carbolic acid administered in febrile cases in sufficient doses always lowers the temperature suddenly. 2. The temperature may be kept down by fresh doses of the medicine at will. 3. Doses of carbolic acid heretofore considered toxic may be surpassed without danger. Some of Dr. Desplats's patients have taken for many days continuously eight, ten, and twelve grammes of carbolic acid.

Charcoal in Infantile Diarrhœa.—Dr. Jules Guérin recommends the employment of finely-powdered charcoal, given in the nursing-bottle with milk, for the diarrhœa of young children: a dessertspoonful is sufficient. He has recently cured a case of diarrhœa with vomiting by this means.

A Premonitory Symptom of Uræmia.—Dr. Ortille (*La France Méd.*, 1880, p. 579) says that uræmia is one of the possible modes of termination of uterine cancer, occurring as a consequence of the obstruction of the ureters from the growth. A premonitory symptom of this condition is the sudden and total disappearance of all pain. Dr. Ortille further asserts that uræmia is not a poisoning,—that is, an

alteration localized in the blood or one of the principal tissues,—but is a cachexia,—that is, a general trouble involving all the organs.

Excitability of the Vaso-Motor (Vaso-Dilatator) Centres in the New-Born.—We know already that the excitability of the nervous system in the fœtus is somewhat different from that of the adult. Soltmann found that the electrical stimulation of the cerebral cortex was not followed by any effects before the tenth day of extra-uterine life. This fact was well established also by Farchanoff. I may add that the excitability commences afterwards to increase moderately until the nineteenth day, when an epileptic attack can be produced by an electric current. The excitability of the motor nerves in the newborn to the electric stimulus is not so great as in the adult, and goes on augmenting until the fifth week (Soltmann). Somewhat later the same writer proved that the cardiac inhibitory nerve-centres were very little or not at all developed at birth, because stimulation of the pneumogastric produces only a little retardation of the pulse. Anress obtained the same results in cats, in which the activity of these centres appeared from the seventh to the fourteenth day.

The above experiments incited me to the study of the vaso-motor system. The following is my experience on cats and dogs:

I. Experiment on a pup born the previous night. On electrical stimulation of the lingual nerve, no alteration at all was noted in the organ. The sympathetic of the right side was cut, and some increase in the heat of the corresponding side of the head and ear was noticed, though in a slight degree. The duct of Wharton was then divided, and viscid saliva began to flow, and, on cutaneous injection of pilocarpin, a copious salivation occurred.

II. In another pup, of the same age, no alteration occurred on stimulation of the lingual nerve.

III. In another pup, similar to the previous ones, on stimulation with a weaker current dilatation of the vessels of the tongue occurred, accompanied with the same phenomena as in the adult.

IV. A pup born in the preceding night. On stimulation no alteration was noted.

V. In a brother of the previous pup, on stimulation of the right lingual nerve a notable dilatation of the lingual vessels of the same side was observed, the surface assuming a very prominent, bright color, the corresponding margin of the tongue appearing larger.

VI. In a cat three days old, no alteration was observed on stimulation.

I conclude that the vaso-motor centres as well as the inhibitory are not sensible to stimulation on the first days of extra-uterine life.—*Extract from Giornale Lo Sperimentale*, 1880. P. B.

Parotitis as a Complication of Ovariotomy.—R. Möricke (*Zeitschr. f. Geburtshülfe u. Gynäkol.; Cbl. f. Chir.*, 1880, p. 667) says that the not very uncommon concurrence of parotitis and inflammation of the testicle has its analogue in the female sex, certain cases having been recorded where parotitis followed or became interchanged with disease of the female sexual organs. Among two hundred ovariotomies reported by Schröder, parotitis was observed in five cases; only one of these could be referred to infectious disease, consequently there could be no question of metastasis. The enlargement began in one case on the fourth day, in the other cases from the sixth to the seventh day. In three cases suppuration of the parotid gland occurred. One patient died of this affection, so that in debilitated individuals it may be regarded as a serious complication of ovariotomy. The relationship of the two affections is difficult to understand.

Laparotomy in Pregnancy.—In two hundred ovariotomies C. Schröder (*Zeitschrift f. Geburtshülfe u. Gynäkol.; Cbl. f. Chir.*, 1880, p. 667) made seven in pregnant women. All seven terminated favorably for the mother. In four cases the women went to term, which is not unfavorable when it is considered that a living child could have been expected in only one case without ovariotomy. After remarking that only with the help of every means of diagnosis can the existence of the complication of ovarian tumor and pregnancy be made out, Schröder concludes that the operation is a justifiable one. On account of the development of the venous circulation in the broad ligament during the later months of pregnancy, the most favorable period for operation is the earlier one. Six months after delivery is, according to Schröder, the earliest moment at which the operation should be undertaken.

Speaking of the simultaneous occurrence of pregnancy and uterine myoma, Schröder alludes to the extreme difficulty of diagnosis, and, after mentioning the difficulties in the way of a birth at full term in these cases, which authorize the physician to bring on abortion, he gives a case in which he performed myotomy on the gravid uterus at the end of the sixteenth week of pregnancy. The tumor was a large pedunculated, subserous myoma, which was connected with the omentum and with two small subserous myomata. The extreme distress to which the growth of the uterus and of the myomata gave rise indicated the removal of all these myomata. The result was favorable, and birth was completed at full term with the aid of the forceps.

Primary Carcinoma of the Lymphatic Glands.—E. Chambard (*Rec. Mens. de Méd. et de Chir.; Cbl. f. Chir.*, 1880, p. 670) gives the case of a cachectic woman of 63, in whom, on examination, both axillæ and both supra-clavicular regions were found full of hard nodules of various sizes, movable and immovable, which were evidently enlarged lymphatic glands. At the under boundary of the right axillary group of lesions a pea-sized scirrhus of the skin was found. The whole left arm, in the axilla of which the lesions were most marked, was œdematous. *Both mammæ were intact.* Two months later, the disease had made decided progress; both the breasts were unquestionably carcinomatous, and in the skin of the left mamma numerous scirrhous tumors could be seen. Ulceration took place in the axillæ, and the patient died some four weeks later. The autopsy revealed, in addition to the lesions above mentioned, extensive tumors of the lymphatic glands in the anterior mediastinum, metastatic tumors in the outer surface of the pericardium, both lungs, the liver, the capsule of the right kidney, etc. Microscopic examination showed these to be carcinomatous. Chambard concludes the case to have been one of primary carcinoma of the lymphatic glands.

Tumor of the Mesentery—Gastrotomy—Recovery.—A Parisian of constipated habit, but of good general health, was seized with violent abdominal pain of an intermittent and excruciating character. Failing to gain relief, he was operated on by Dr. Tillaux by gastrotomy, with antiseptic precautions. On opening the abdomen, a tumor the size of a fœtal head was discovered, involving the mesentery, and was removed. On examination, this tumor was found to be cystic, and filled with fatty matter. The patient made a good recovery. —*Bull. Gén. de Thérap.*, vol. ii., 1880, p. 229.

Milk Diet in Heart-Disease.—Dr. Potain (*Bull. Gén. de Thérap.*, vol. ii., 1880, p. 232) says that milk diet is particularly efficacious in secondary affections of the heart, hypertrophy or simple dilatation of renal or gastric origin. This regimen acts on the stomach or kidneys by affording complete repose. It should be continued for a long period. It is useful also in simple reflex palpitation of gastric origin. In order to be efficacious, the milk regimen should be well borne by the stomach. Three quarts daily appears to be the proper average amount to be ingested.

Syphilitic Neuralgia.—Dr. Mauriac employs the following formula:

℞ Pulvis iodoformi, ℈i;
Ext. et pulvis gentianæ, q. s.
Fiat in pil. no. xx.—M.

Two or three to be taken daily.

Formula for Hypodermic Use in Syphilis.—Dr. Yvon (*Bull. Gén. de Thérap.*, 1880, vol. ii., p. 217) recommends the following as not exciting local irritation, not coagulating albumen, and as easily absorbed:

℞ Hydrarg. biniodid., } āā gr. xv;
Potassii iodidi, }
Sodii phosphat. (tribasic), ℈iss;
Aquæ destillat., f℥xii.—M.

Six minims of this solution will contain one-eighth of a grain of the mercurial salt.

Treatment of Gaseous Dyspepsia.—In this form of dyspepsia, accompanied by fermentation with the rapid disengagement of large volumes of gas after meals, the most satisfactory remedy is chloroform, in the dose of fifteen to twenty drops in a little syrup. After a few moments the gas is expelled from the stomach and fermentation arrested.

Treatment of Phthisis by Creasote.—M. Boyer administers the creasote as follows: Creasote, ℥ij; rum, ℥iv; glycerin, ℥iv; one or two tablespoonfuls to be taken daily after meals in a little soda-water. It is in the torpid and scrofulous forms of phthisis arrived at the second stage that M. Boyer uses the above mixture.

MEDICAL TIMES.

PHILADELPHIA, DECEMBER 4, 1880.

EDITORIAL.

THE SECRETS OF THE CONSULTING-ROOM.

WE earnestly ask our readers in this State that they will use their personal influence to secure the passage of a law by our Legislature recognizing the relation between the doctor and the patient. The secrets of the lawyer's consulting-room and of the priest's confessional are held inviolate by the law. Is not the relation between physician and patient as delicate and as important as that between lawyer and client? are not the revelations known to be necessary for the cure of the ills of the body as worthy of the recognition of the law as are those believed to be necessary for the cure of the ills of the soul?

A law of the character spoken of has existed in New York since 1828, and is said by the Medico-Legal Society of the State to have worked well. It is now proposed to copy this enactment in our State. The text of it is as follows:

"No person duly authorized to practise physic or surgery shall be allowed or compelled to disclose any information which he may have acquired in attending any patient in his professional character, and which information was necessary to enable him to prescribe for such patient as a physician, or to do any act for him as a surgeon."

The medical profession can, if it will, mould legislation in regard to itself. What is wanted is *individual* effort by the doctors through the State. You physicians who recognize the importance of the law, make it a point to see personally, or, if this be impossible, to write urgently to, your representatives in the two legislative bodies, and pledge them if possible.

Some years since, when working for an appropriation to one of our hospitals, we went to Harrisburg with a well-known politician and lobbyist. The question was asked, Shall we depend upon seeing the committee and the Legislature, which had appointed an hour for seeing us? "D—— this shooting into flocks; pick out your bird," was the reply. Not much piety, but much worldly wisdom,—the very secret, indeed, of successful lobbying.

THE raids of American publishers have been sufficiently violent in their disregard of the rights of English authors, but we doubt if any acts can be found which will quite parallel the recent doings of an English firm. The well-known series of American Health Primers are apparently being republished in London *in extenso*. This is certainly complimentary to their authors; but, unfortunately, the authors' names are suppressed and every effort made to give the impression that the books have been written in England. The series appears as "Ward & Lock's Long Life Series," and is announced as "accurately written and carefully edited by distinguished members of the medical profession." Four of the republications have reached this country. In Dr. White's book there is but a single alteration, in Dr. Harlan's one, in Dr. Cohen's eleven, whilst in Dr. J. G. Richardson's changes are made on no less than thirty-seven pages. Two or three of these modifications are slight verbal corrections, whilst the others are of such a character as to show that they were made for the purpose of concealing the American origin of the books.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held at the hall of the College of Physicians, Philadelphia, October 13, Dr. Albert H. Smith, president of the Society, in the chair.

Dr. George Hamilton read a paper entitled "Hemorrhage incident to Parturition" (see No. 339, page 99).

Dr. Blackwood, in opening the discussion, inquired how long it would be advisable to allow a placenta to remain before removing it, in the opinion of the lecturer.

Dr. Hamilton said that no inconvenience resulted from the placenta remaining a considerable length of time. In one of the cases he had reported it remained for thirty-six hours without doing any harm. No regular time can be laid down, but it will vary with special cases.

Dr. Packard said that there were two or three points that had occurred to him while listening to the paper. First, is post-partum hemorrhage, with the practitioners of medicine in this country, a matter of such frequent occurrence? It would seem, from the discussion of the matter in the English journals, that the number of cases must be entirely out of proportion to that which we meet with here; whether owing to mode of living, the climate, or other conditions, he could not say. Secondly, he inquired whether delivery of the placenta by Crédé's method is not so generally followed by physicians as to do away with methods formerly in vogue? thirdly, whether the administration of ergot after the uterus has been emptied is not the correct mode? and, finally, whether the injection of hot water has not been a success in the hands of the members present who have employed it in the treatment of post-partum hemorrhage?

Dr. William Goodell admired the candor with which the cases had been reported by the lecturer. The two cases were diverse, and would have tried the skill of any physician. In the first case he would not say how far the manipulation was wrong or right, but his own practice would have been not to have disturbed the woman as long as there was no bleeding. If hemorrhage occurred, the only thing to be done was to deliver. However, he did not know that anything better could have been done than was done. He considered it a case of concealed accidental hemorrhage, in which a good deal of blood had been thrown out under and around the placenta, and had been subsequently expelled. Some years ago, in writing a paper on this subject for the Obstetrical Society of this city, he had looked up the statistics bearing upon this complication of labor, and had found that the mortality was frightful.

The second case was a bad one of post-partum hemorrhage, and, having no treatment, the patient was virtually moribund before the physician arrived, and he had no chance. The first thing to do in such cases is to relieve the woman,—empty the uterus and then resort to ice or hot water.

The subject of hemorrhage incident upon parturition was such a great and important one that he scarcely knew where to begin and where to end, but, as he had been asked for his experience, he would give his own rules of practice. In regard to the removal of the placenta, he usually delivered it by Crédé's method as soon as the womb was sufficiently contracted. If a woman is known to be a bleeder, it is important to take some measures to prevent hemorrhage. His own practice was to give a good dose of ergot and a good one of quinine towards the end of labor, and to delay the descent of the shoulders and body so as to secure good contraction of the uterus. When the child's body is partly born, slapping the shoulders will cause convulsive movements of the legs, which will stimulate the uterus and make it contract.

He always gives ergot immediately after delivery in a primipara, and as soon as the perineum begins to bulge in multipara, not only with a view of preventing bleeding, but also to hinder the absorption of putrid lochia. Ergot is thus a good remedy when given in time, and especially so in bleeders. He recalled the case of a lady, the wife of a physician, who had a history of severe post-partum hemorrhages, and who had also taken chloroform in her two previous labors. He determined not to give chloroform on this occasion, but was obliged to yield to the entreaties of the family. He, however, stipulated that she should have full doses of ergot. During the second stage of labor the husband was directed to give a teaspoonful of the fluid extract of ergot. After the birth of the child a hemorrhage of the most formidable character took place. It was simply frightful. He had never before seen a patient recover from such a loss of blood. To add to the difficulties of the case, the woman became maniacal from the effects of the chloroform, and rolled from side to side of the bed, shrieking and screaming. The hemorrhage was finally stayed, and she rallied, but only under full doses of opium. It was hours before the pulse at the wrist came up so as to be felt. The husband afterwards acknowledged that, fearing the impressibility of his wife's constitution, he had given only ten drops of ergot, instead of the full dose ordered.

This brings up the question of anæsthetics in obstetrical practice. From his own observation he believed them dangerous, and especially so when ether is given. Chloroform can be administered at the beginning of a pain, and withdrawn immediately after it has passed. But if ether is used its full anæsthetic effect must be maintained between the intervals of the pains, or else the pains are felt more keenly. Hence the womb is liable to become relaxed from prolonged anæsthesia, and the danger to the patient is much greater than where it has not been given or chloroform has been used.

In post-partum hemorrhage he invariably gives ergot. Where it is anticipated he always gives a teaspoonful of fluid extract of ergot when the head has cleared the os uteri. He always follows the womb down with the hand, and if

there is any hemorrhage removes the placenta by expression as soon as the womb has contracted. If, however, the hemorrhage is dangerous, he delivers the placenta at once, and then resorts to lumps of ice within the cavity. This he had generally found to be efficient; but he always held the hot water in reserve. He would, however, make the addition of vinegar to the hot water. Of the value of vinegar as a hemostatic there is no doubt. He had found it of great service after the removal of large growths in the enucleation of fibroid tumors of the womb, and particularly in operations on a cancer of the womb, as well as in ordinary operations, when the bleeding interferes with the progress or the success of the operation. He fully endorses Prof. Penrose's championship of its utility in labor, but would suggest the combination with hot water as being doubly efficient. Having a wholesome fear of the subsulphate and the tincture of the chloride of iron, he would reserve their use to such desperate cases as resist the ice and the usual remedies. He feared these remedies, because, in a very bad case, some years ago, he injected the iron and promptly stopped the hemorrhage, but septic peritonitis rapidly ensued and carried off his patient. This untoward result he attributed to the decomposition of the plaster-like clots formed in the uterine cavity by the iron, and left behind.

Dr. D. M. Barr did not believe that anæsthetics increased the liability to hemorrhage, and from his own experience was satisfied that a proper anæsthesia not only does not interfere with, but, on the contrary, favors, the use of means to arrest hemorrhage. The patient is passive, manipulation meets with neither excitement nor resistance, and unless the anæsthetic effect be too profound, beyond what should ever be used in the lying-in room, the uterus will respond as promptly in the anæsthetized state as in its absence.

He had used anæsthetics largely in labor cases, and had never seen contractions interfered with or hemorrhage induced by them, and stated that similar testimony is not wanting from those who have used anæsthetics over thirty years continuously.

He had one case of death from hemorrhage, after a premature labor, induced by the mother at eight months. Cold water was poured upon the abdomen, and ice was introduced into the cavity of the uterus, in accordance with the teaching at that time,—fifteen years ago,—but contractions failed to set in, and the woman bled to death as from a loose bag. No anæsthetic was used in this case. Carbolized hot water would certainly seem to be the more rational treatment, but was not dreamed of then.

In a recent case of placenta prævia, in which the woman was almost bloodless from repeated hemorrhages, and in the face of a copious hemorrhage at the onset of labor, she was anæsthetized, the child turned, and the hemorrhage controlled as perfectly as though she had suffered all the agonies which pertain to turning under ordinary circumstances.

If these facts be true, is not woman entitled to the benefit of anæsthesia in labor? and should not our teachers and leaders in medicine rather instruct in the proper use than forbid the use of this comfort?

Dr. Addinell Hewson said that in the place of the ordinary anæsthetics he had been in the habit of inducing analgesia by rapid breathing, which can be instituted at the onset of a pain and suspended in the intervals. There is no interference with the action of the uterus by it, and no difficulty is experienced in any operation requiring the co-operation of the patient, for the patient is not unconscious, although free from suffering. He recommended a further extension of this method in obstetric practice. In regard to the use of ergot hypodermically after delivery, he said that he used it so constantly with satisfactory results, while the patient was insensible from the rapid breathing, injecting the remedy into the back part of the thigh, and had found it to be much more efficient so than when given by the mouth.

Dr. William T. Taylor, in referring to Crédé's method, said that it was suggested to him and practised by Dr. Charles M. Griffith about twenty-five years ago, the recommendation being to squeeze the uterus and force the placenta from it.

Dr. Charles B. Nancrede differed from Dr. Barr, and was satisfied that anæsthetics do stop the pains of labor.

Dr. W. H. Parish remarked that one point brought out by the lecturer was in reference to the need of immediate interference in cases of active bleeding, especially post-partum bleeding. Dr. Parish believed in the necessity of active interference. The question of removal of the placenta is the first presenting itself. If allowed to remain, it can be of no service, and may be of much harm. The hemorrhage usually comes from the placental site. The uterus cannot fully close the bleeding orifices except by complete contraction, and this will not occur until after its cavity has been emptied. The so-called Crédé method, according to Barnes, was in vogue in Great Britain prior to the association of Crédé's name with the procedure. This method is the best one, although not invariably successful.

When the bleeding is from the placental site, it ceases after the removal of the placenta and the full contraction of the uterus. In some cases the bleeding is from a lacerated cervix; in such a case Crédé's method has a special advantage over the introduction of the hand, inasmuch as the latter may increase the tear and add to the hemorrhage. He related a case in which the physician left

a retained placenta in the uterus and vagina, and when seen by Dr. Parish, twenty-four hours after the birth of the child, the after-birth was in a state of putrefaction. He would not, therefore, be willing to leave a placenta for thirty-six hours after labor, as had been done by the lecturer, but believes in its immediate removal if hemorrhage exists.

He had been impressed with the value of hot-water injections, and from experience he believes that they have special advantages. Ergot, which is indispensable in all the forms of hemorrhage, and should be administered when there is laceration of the neck, will not, however, in the latter condition, check the bleeding. Hot water injected against the cervix and into the uterus will stop this bleeding, aid in keeping the womb in contraction, wash away blood-clots, and diminish the danger of septic poisoning.

Where the patient has lost blood until exhausted, ice or cold water and ergot do not suffice to stop the bleeding with sufficient promptness. In this condition hot water injected into the cavity of the womb will secure immediate uterine contraction and promptly stop the bleeding.

In two or three hospital cases he had, a few years ago, injected into the uterus to control post-partum hemorrhage a weak solution of Monsel's salt. The patients recovered without symptoms necessarily dependent upon the injections. He would not now, since he has learned the value of hot water, resort to such a remedy as Monsel's solution by injection. In a case of placenta prævia he saved the child by rapid delivery after podalic version, and saved the mother from impending death from hemorrhage by carrying a piece of cloth saturated with Monsel's solution into the uterus and swabbing the placental site.

Dr. Atkinson endorsed the opinion of Dr. Goodell as to the value of Crédé's method; but Dr. Atlee had taught and employed it as early as 1853, long before Crédé recommended it. Hot-water injections he uses with great satisfaction, had never needed to add vinegar; as a prophylactic he generally gives quinine and ergot. He had noticed that there was a liability to hemorrhage in women who have a varicose condition of the veins of the vagina and neck of the uterus; and he has now a case under observation in which there has been very decided hemorrhage in previous labors.

Dr. Goodell said that he would like to make a single remark more. In regard to Crédé's method of delivering the placenta, it was stated by Dr. Parish, who quoted Dr. Barnes of London, that this method was taught and practised in the Dublin school many years ago; but the Dublin school merely placed the hand above the uterus, and followed it down as it contracted. Crédé's method, however, is more than this: it is, in addition, the expression of the placenta by forcibly squeezing it off and out of the womb by the hand. The placenta is thus forced out like the stone from a cherry when pinched between the thumb and forefinger. He did not believe that this plan had ever been practised by Dr. Atlee or by any one else before it was devised and recommended by Crédé; at least such a plan had never been described or published by any other physician.

Dr. Hewson said that when he was a resident in the Rotunda Hospital, Dublin, in 1851, the method then taught there was similar to that mentioned by Dr. Goodell, of following down the uterus and not of squeezing the organ with the hand.

Dr. W. R. D. Blackwood recommended the hypodermic injection of ergot as the only serviceable method. In one case, after giving without result two ounces of Squibb's ergot by the mouth, he had injected one drachm hypodermically, and the hemorrhage stopped at once.

In a practice of twenty-three years he was satisfied that the use of anæsthetics does tend to produce post-partum hemorrhage: he therefore uses them only where absolutely necessary, as in instrumental delivery.

With reference to the propriety of leaving the placenta when adherent, he reported the following case. While at Huntsville, Alabama, in 1867, he was called to see the wife of a hospital steward with retained placenta after delivery. He insisted upon its removal, but was overruled. In eighteen hours septic symptoms set in, and in a few days the woman died of septicæmia. He had experience in other cases, and now is not satisfied until he has introduced his hand and peeled the placenta completely from the uterus, and satisfied himself of its *absolute* removal. He was so fully satisfied of the importance of the extraction of the placenta that he would rather invert the uterus, if necessary in order to peel off the placenta, than leave any part of it in to poison the patient. This statement he made deliberately, and would at another time support it by the history of a case in point.

Dr. W. S. Stewart insisted upon a digital examination in cases of hemorrhage, for a portion of the membranes or a clot may act as a wedge to keep the uterus from contracting, and open the vessels which had been already closed. If neglected, it may produce fatal hemorrhage or convulsions. He recalled the advice of the late Dr. Meigs to a young physician, "to go to church once a day, and don't forget to turn out the clots."

Dr. Wm. M. Welsh spoke of a case illustrating the value of vinegar in post-partum hemorrhage. The fœtus of eight months had been dead several weeks; bleeding continued after delivery, applications of ice failed, but vinegar stopped it at once.

Dr. Albert H. Smith said that he had

brought the subject of the use of hot water in post-partum hemorrhage to the notice of the Society some time ago; he had seen no reason to change his opinion of the value of the practice which he then held; on the contrary, his experience had steadily confirmed and increased the good opinion then expressed. One point had not been brought forward in this evening's discussion that is of special importance,—the use of hot water in every case after delivery as a prophylactic against hemorrhage. He would now believe that he had not done his duty to his patient if he had not at hand a syringe and a vessel of hot water, with about two per cent. of carbolic acid, ready for use immediately after delivery.

He recalled a case analogous to Dr. Goodell's, also the wife of a physician, that he had attended. There had been violent hemorrhage in two labors, so that after the second labor she was obliged to lie with her feet higher than her head for two days before reaction was established. In the third labor he used hot water in the manner described as a prophylactic. Having delivered the placenta by the method now called Crédé's, the moment it was delivered he had the hot water ready and injected about a quart. The uterus contracted at once, there was no bleeding, and the secondary hemorrhage which had occurred in her previous labors did not appear. The case progressed like an ordinary normal labor.

The one great advantage in the use of the hot water is that it washes out the uterus, bringing away all coagula and shreds of membrane which often form the nucleus for fresh coagulation. This he regarded as very important, and now always uses it after labor without exception. In a large number of cases the bleeding comes from a clot or mass of blood in the mouth of a large vessel at the placental site. The contraction of the uterus, and closure of the mouths of the vessels, are necessary to prevent post-partum hemorrhage. If the clot remains distending the mouth of the vessel and projecting into the uterine cavity, it is practically the same condition as where the placenta blocks up the mouth of the uterus, as mentioned by Dr. Parish: the uterus cannot completely close, the patulous vessels do not collapse, and the blood continues to pour forth in excess, coagulating and accumulating, until suddenly the whole uterus relaxes. If this is overlooked and neglected and a complete clearing-out of the uterus not insured at first, bleeding may occur in the course of a few hours after the physician has left the house, and the patient may lose her life before he returns. He had never yet seen the case in which the hot water had been used where secondary hemorrhage appeared.

In hemorrhage, also, from the neck of the uterus, which, as has been already stated, occurs from a different cause from that in the cavity of the uterus, namely, from a laceration of its tissue, hot water is very serviceable; it is both very efficient and easy of application. He thought that by its aid post-partum hemorrhage is shorn of its terrors, for now we need not be afraid of its appearance, having a syringe and a pitcher of carbolated hot water ready for injection.

Dr. M. O'Hara, in reply to Dr. Packard, said that he did not think post-partum hemorrhage is very common in this country: in a large practice he had seen it in very few cases. He inquired whether tincture of iodine is now used for intra-uterine injection, as it was very much praised a few years ago in post-partum hemorrhage. In regard to Crédé's method, he had not been able to detach the placenta in some cases by this means, and was obliged to introduce his hand. He recalled a case reported by the lecturer some years ago to this Society, in which about one-third of the placenta was allowed to remain in the uterus on account of adhesions, and gave no further trouble.

Dr. George Hamilton said that he well remembered the case mentioned by Dr. O'Hara: one-third of the after-birth remained in the uterus. The woman gave birth to the child three or four weeks before it was expected; the fœtus was still-born, the placenta adherent. There was no hemorrhage of any consequence in this case, although it was necessary to introduce the hand up to the fundus of the uterus on the left side and tear off the placenta. He could not succeed in removing it all, there was so much hardness and toughness of the placenta; only about two-thirds came away. There was still no hemorrhage. Having consulted several friends upon it, he decided to leave the remainder in. Dr. Carson agreed with him that it was not justifiable to use any more force. He afterwards saw Dr. Goddard, who insisted that it must come away. He tried it again, but failed. Nothing adverse happened; the woman got over it, and could not afterwards remember that she ever passed away any more fragments.

In many cases he had left the placenta in for twelve or eighteen hours without bad results. In the second case included in the paper there was not much hemorrhage at the time, but she had previously lost a great deal of blood.

Dr. Blackwood read a paper on "Anthracæmia." (See No. 339, p. 102.)

A vote of thanks to Dr. Hamilton and Dr. Blackwood was unanimously passed.

TRI-STATES MEDICAL SOCIETY.

PROCEEDINGS OF THE SIXTH ANNUAL SESSION.

Held at LOUISVILLE, November 9, 10, 11, and 12, 1880.

Reported for the *Philadelphia Medical Times* by A. H. KELCH, M.D.

THE Tri-States Medical Association began its sixth annual session in Louisville, November 9, 1880, at the Masonic Temple, there being present at the opening perhaps fifty visitors from different portions of the States included by the organization.

The forenoon session of Tuesday was devoted to the deliverance of addresses of welcome by the municipal and State officers and members of the medical profession, and to the transaction of necessary business, such as the reports of the various officers and committees. This business being speedily dispatched, the afternoon session began the regular work of the programme. Dr. H. V. Black, of Jacksonville, Ill., read a paper on the "Histopathology of Scarlet Fever," the notable points in which were that the doctor holds the view that the tissues of election by the disease are those evolved from the external and internal blastodermic membranes, and that when the disease extends to tissues more or less widely differentiated from these it is accompanied by a radical change in the character of the inflammatory process peculiar to the disease; that the desquamation extends to the alimentary tract, and that this theory will account for many of the sequelæ of scarlet fever, which many regard as complications, while they are in fact intrinsic phenomena of the disease. Thus the affection of the kidneys, he says, while a grave lesion in some cases, is none the less a factor of the disease in all cases.

Dr. J. B. Richardson, of Louisville, read a paper on the subject of "Tubercular Cerebral Meningitis," and under the call for volunteer papers Dr. William H. Wathen, of Louisville, read a paper on "Lacerations of the Cervix Uteri."

The address of the president, Dr. H. B. Buck, of Springfield, Ill., was delivered at 7.30 P.M., after which it was announced that Dr. S. W. Gross, of Philadelphia, would favor the Society with a paper, which he did on the following morning, on the subject of "Malignant Tumors of the Mammary Gland." The paper was founded on the facts contained in the work of Dr. Gross on this subject.

Dr. B. M. Griffith, of Springfield, Ill., read a paper on "The Practice of Medicine," touching upon the various theories as to the causes and treatment of disease as each has presented itself and had its day of preference. After Dr. Griffith came Dr. Horace Wardner, of Anna, Ill., president of the State Board of Health. Dr. Wardner read an interesting paper on "State Medicine."

At the afternoon session Dr. Dudley S. Reynolds, of Louisville, exhibited Snellen's *Phacometer*, constructed by Kaganaar, of Utrecht, and an improved form, constructed under the direction of Prof. Reynolds, by Cook & Sloss, of Louisville. The improvement to which attention was called consisted in the addition of a graded dial attachment to the sliding register. The advantages of this improvement are found chiefly in measuring cylindrical lenses, the axes of which appear instantly on observing the luminous points upon the register, noting only the direction of the lines which show the axes of the lens. A great addition to the convenient manipulation of the phacometer was made by Cook & Sloss, who placed a box over the beam of the instrument extending from the lamp to the centre of the beam. In the plate which holds the two lenses are fastened on each side brass rods pointing directly in the horizontal line, upon which the frames of spectacles to be tested may rest. This secures absolutely invariable relations between the spectacle lenses and the register on the dial-plate. An improvement has also been made in the clasp, which is now made to work by a spring attachment, which holds the jaws of the clasp gently together and allows separation of them without any opening of the stem. The bellows attachment extends from the dial-plate of the proximal lens at the centre of the beam, and, as the ribbon is made to draw the dial-plate towards the centre, the bellows arrangement admits of simple folding of the apparatus, thus constituting a telescopic tube of folding capacity as well as that of extension. The value of the phacometer for testing spectacle lenses can scarcely be appreciated by those unacquainted with the instrument. The spectacle lenses commonly found in the shops rarely have uniform refracting powers. They generally show in the direction of one of the crossed lines of luminous points a want of symmetry, and have rarely, in the quadrants brought under observation by the phacometer, an equal amount of refracting powers. This announcement proved somewhat astonishing to a number of the gentlemen present, and several pairs of spectacles were at once passed up to the stage for examination, but one pair of which was found to be correctly graded. It was announced that most of the lenses in oculists' test cases put up by the best and most celebrated manufacturers are incorrectly graded, and whilst the lenses themselves may be perfectly symmetrical, having definite and distinct refracting powers, they do not correspond to the figures stated upon their margins.

The method of calculating the powers of lenses by their radii according to the metrical system has proved unsatisfactory, as the dioptra, which is the basis of the calculation, is itself an indefinite quantity. The only suc-

cessful method of grading lenses is by the adoption of a system governed by the foci of the lenses themselves. For example, in grading a series of lenses it should be borne in mind that it may be necessary to recognize such as have refracting powers sufficient to focus light at the distance of about three-sixteenths of an inch from each other, bearing in mind that this space is a fraction less than the grades of high refracting lenses marked one-fourth. We are then prepared to recognize such as correspond to some definite mathematical scale of projection in refracting power, without attempting to measure actually the radius of curvature upon the surface of a transparent body of small dimensions. The phacometer offers a practical test of the real effects produced by compounding lenses. It affords an invaluable method of testing the practical result of all optical calculations for the correction of defects of refraction in the eye. It may thus be seen that the phacometer is an invaluable aid to the oculist as well as to the optician, and that the improvement proposed in the grading of the dial-plate, upon the surface of which the luminous points are projected, forms one of the most useful features of the instrument, for without this it would be extremely difficult to determine the axes of cylindrical lenses; and it is this class of lenses above all others which require graded measurements.

Dr. J. R. Weist, chairman of the section on Surgery, next read a paper on the subject of "Bronchotomy for the Extraction or Relief of Foreign Bodies in the Air-Passages;" under the term bronchotomy were included all operations by which the larynx and trachea are opened. Dr. Weist from the results of a study of eight hundred and seventy-eight cases arrives at the conclusion that the surgical rule proposed by Dr. Gross lacks the confirmation of experience. While the statistics of Dr. Gross show nearly a double percentage of fatality in those cases not interfered with over those in which operations have been performed, the statistics of Dr. Weist show but two per cent. in favor of such operations,—a percentage not sufficient to warrant operative procedures. The following conclusions are reached by Dr. Weist. First, when a foreign body is lodged either in the larynx, trachea, or bronchial tubes, emetics should not be employed, as they increase the sufferings of the patient without effecting an expulsion. Second, inversions of the body are dangerous, and should not be practised unless an opening has been made in the trachea. Third, when symptoms of suffocation are imminent, an operation should be employed at once; also when dyspnœa is progressive. Fourth, when the foreign body is movable up and down the trachea an operation is indicated. Fifth, while a foreign body excites no dangerous symptoms, tracheotomy should not be performed. Sixth, while a foreign body remains fixed in the trachea (modifying conditions above given excepted), tracheotomy should not be performed. He warned against the dangers of hurried operations, and closed the paper with a general description of the operation not differing materially from what is authorized by surgical writers.

Dr. George B. Walker, of Evansville, Ind., chairman of the Obstetric section, read a paper on that subject, in which he dates its birth as a science from the time when "turning" was first advocated. He held the view that with the advantages given the operator by a thorough knowledge of this procedure, the indications for the use of the forceps were very few. Indeed, he is inclined to believe obstetrics would not have been materially deficient had they not been introduced, and he thinks that in a vast majority of cases the short, straight forceps will meet the indications. Post-partum injections of medicated solutions may be regarded as meddlesome midwifery. Quinine is regarded as a stimulant and excitant of uterine contractions, and ergot in the hands of intelligent men is approved. The more serious operations in connection with the subject were alluded to, the views of the author coinciding with those of established authority.

Dr. E. W. Jenks, of Chicago, chairman of the section on Gynæcology, read a paper on "The Relations of Goitre to Pregnancy and the Generative Organs of Women." He says, "That the thyroid gland is in close sympathy with the uterus is acknowledged by both ancient and modern writers." The author, "having seen many cases of enlargement of the gland in young girls about the age of puberty, and among the cases appearing at his clinic, where the affection could be traced directly to disorders of the generative system, was led to believe the subject worthy of study." He tersely remarks that "while most authorities attribute the affection to the geographical conditions of a country, yet when it comes to establishing those conditions there is a universal diversity of opinion." Dr. Jenks apologized for the brevity of the paper, which might have been continued to the gratification of those present.

The usual banquet was held on Wednesday evening.

On Thursday morning, Dr. David Prince, of Jacksonville, Illinois, read a paper on the "Dressing of Wounds." The principal feature of the paper was the advocation of treating lacerated and contused wounds that necessarily cause great loss of substance from slough by immersion, when possible, in a solution of salicylic acid, the proportion being $\frac{6}{1000}$, or of carbolic acid $\frac{1}{100}$. This immersion is to be constant throughout the whole treatment, when the situation of the wound will admit of it. Otherwise, frequent irrigation with the same solution is advocated (every twenty minutes). Cases were detailed where the results had been highly gratifying

after a treatment by constant immersion extending over one hundred and twenty-two days.

Dr. Wm. Dickinson, of St. Louis, read a paper on Hemiopia,—mechanism of, causation of, on the theory of total decussation of fibres of the optic tracts at the chiasma. Dr. Dickinson worked out the subject very clearly and comprehensively, and succeeded in convincing the audience of the correctness of the theory.

Dr. C. H. Hughes, of St. Louis, read on the subject of "Psychiatry." Dr. Hughes thinks that at present too many cases of mental aberration are sent to asylums for treatment. The question of consignment to an asylum may be more satisfactorily answered by attention to the following questions: "Is the patient so regardless of the proprieties of life as to render him unfit to remain longer at home?" "What antipathies has he for those by whom he is surrounded, and is there danger to wife, husband, or child?" "Can the patient be treated and cured by medicine alone?" "How long would it be safe to treat a patient in the midst of those surroundings which may have excited the malady and still contribute to aggravate it? are any such conditions removable?" "Does the patient persistently refuse food, and is his condition in many or most respects such as to require those agencies, appliances, gentle restraints, and constant surveillance which only a good and well-appointed hospital can give?" "How can the physician approach daily and treat the patient without incurring his dislike?" An intelligent and correct answer to such questions Dr. Hughes thinks would enable physicians to avoid many of the evils of the too indiscriminate consignment of patients to insane hospitals. He then proceeds to speak of those who are the proper subjects for asylum treatment, and among these he includes cases of puerperal insanity, many hopeless cases of which he thinks justly attributable to the inadequate nourishment furnished by the post-parturient low diet. Cases of insanity during utero-gestation. This form, by appropriate treatment, may be kept in abeyance until the crisis is past, but these cases require close surveillance to insure the safety of both mother and child, and the asylum is often the only refuge for such patients. Cases of progressive paralysis of the insane, he says, being as happy in one place as another, and seldom or never dangerous, can be treated as well at home as at the asylum. Acute psychic disturbances dependent upon hyperæmia are quickly relieved by appropriate treatment, but had better be treated at an asylum, because they require constant watchfulness. Cases of senile dementia in old men, when harmless, should always be kept out of asylums. Mild cases of melancholia frequently develop into the worst form of insanity, and should always be treated at the asylum. The moral effect exercised by the contemplation of such cases as can be comprehended by these patients will often lead them to abandon their own delusions. Dr. Hughes touched upon the subject of the rights of the insane, and with a few remarks upon this subject closed an excellent paper.

Thursday afternoon, Dr. Williams, of Cincinnati, read a paper on the subject of "Amblyopia from Disuse." He said, While it is true that if for any cause the action of a set of muscles is kept in abeyance they decrease in size and power, this is not true of the organ of vision. Old writers were in the habit of attributing imperfect sight to amblyopia from disuse. Von Graefe was the first to question this. He removed a cataract from the eye of a woman sixty years old, who had been blind in that eye from the age of three years. After the removal the perception of light was immediate, though the function of sight had not been performed for nearly sixty years. That experience inclined him to think that a long cessation of vision does not affect sight. Still, he insisted that cataract from birth, prohibiting the exercise of vision, is liable to be followed by amblyopia from disuse. Hence he advocated an early operation. My own results have been uniformly better from an early operation.

The most frequent form of amblyopia from disuse is that from strabismus confined to one eye. Some have contended that the amblyopia detected in monolateral squint is due not to disuse but to pre-existing congenital amblyopia. Very often, however, the sight of the worst squinting eye from early infancy, even in advanced years, is not perceptibly reduced. In such instances the patient has probably had alternating strabismus. In this affection the ophthalmoscope reveals no defect in the eye, though one may have perfect vision and the other be entirely useless. This is the case in monolateral squint. A curious fact in this connection is that those portions only of the retina become insensible which functionate in normal vision. Besides, the individual acquires the power of suppressing the image of the squinting eye, and in a short time this image is utterly ignored by the mind. Dr. Williams then detailed the case of an old man who had suffered from squint for years who, when his sight began to fail in the fixed eye, by a peculiar process of training acquired the faculty of fixation of the squinting eye, and thus had nearly normal vision restored to him. With the details of another similar case, Dr. Williams closed his very interesting paper.

Dr. William Porter, of St. Louis, read a paper on "Objective Points in the Treatment of Phthisis." Dr. Porter confined himself almost exclusively to the discussion of the self-limitation of phthisis. He took for a basis of discussion the cases presented by Dr. Flint, who said, "Phthisis is self-limited when

it ends in recovery irrespective of extraneous influences derived from either hygiene or therapeutics. Only patients who recover without any potential remedies having been employed, and when there has been no material change in the daily life and habits, can be said to have recovered exclusively by self-limitation." Of the seventy-five cases on which Professor Flint based his conclusions, forty-four ended in recovery, and in thirty-one the disease ceased to progress, in a majority of cases for several years. Of the forty-four cases ending in complete recovery, there was no medicinal treatment, Professor Flint says, to which the recovery could be attributed. Of the thirty-one cases that ceased to progress, the history is that "at the last examination of these cases there was evidence of the disease." These not having recovered, they cannot affect the question. Of the forty-four remaining cases he declines to accept twenty-one of them, because cod-liver oil, one of the most potent agents, had been administered to them. In fifteen of the remaining twenty-three cases hygienic measures constituted the treatment, and this was of the most efficient kind, such as out-door life, travel in Europe, etc. These must be excluded; and if this exclusion be fair and just we have but eight cases remaining. Of these, one became a travelling man, his business involving much exercise in the open air. Dr. Porter continued analyzing the cases until but three were left. He afterwards spoke of the treatment, emphasizing first the importance of thorough exploration of the suspected site of the disease.

"Phthisis being a wasting disease, the important indication," he says, "is to put a stop to the waste or to overcome it;" the measures of treatment then advocated cannot be said to differ materially from what have been advocated in the last three years.

Dr. H. C. Fairbrother, of East St. Louis, next read on the subject of "Mediæval Medicine." He confined his observations to the subject of medicine as practised by and confined to the priesthood. The tenor of his paper was objectionable to several members of the Society, who took it to be an arraignment of the Christian religion from beginning to end.

Dr. Arch. Dixon, of Henderson, Ky., read a paper on the subject of "Arrest of Evolution *vs.* Maternal Impressions." After quoting extensively from physiological authors concerning the development of the fœtus, and after noticing the similarity between the human embryo and that of the lower animals, Dr. Dixon reaches the conclusion that congenital malformations, in which deficiency of structure is apparent, are the result of arrest of evolution. Excess of the same process is made to account for malformations in which supernumerary parts are displayed; and, further, some deformities not attributable to either, he thinks, can very appropriately be attributed to placental inflammation and adhesions.

Dr. W. W. Seely, of Cincinnati, read on the subject of "Non-Astringent Caustic Treatment of Conjunctival Inflammations."

Dr. Seely says, "It was only the most complete conviction of the truth of my experience that led me about three years ago to publish an article entitled 'The Astringent Caustic Treatment of Trachoma: is it Tenable?' My early experience was that the so-called astringent caustic treatment of all conjunctival affections, but more especially the trachomatous variety, was uncertain, as it was difficult of comprehension, painful, and often detrimental.

"Trachoma, as all are aware, has ever been an opprobrium; and it was this disease, especially when complicated with corneal trouble, that first aroused my suspicions that something was radically wrong. These suspicions became so profound that there was quite an interval during which I was at an almost total loss how to act. I finally began to abandon all treatment for the lid trouble when either the cornea was actually involved or there was a marked tendency to it, and simply directed my attention to the so-called corneal complication." He then speaks of the unsatisfactory results from atropia, and of the success that has followed the application of the yellow oxide of mercury rubbed up with lard.

Concerning the cause or causes of inflammations of the conjunctiva, Dr. Seely says that for him the parasitic theory harmonizes with long clinical experience, and there can be no return to former methods of therapeusis. In reference to the action of calomel he says, "I do not know what proportion of oculists accept Donders's explanation of its *modus operandi*, but certainly all recognize its value." He claims that whatever of benefit arises from astringents comes from *indirect antisepsis*.

Dr. Seely now discards in these cases astringents, along with caustics and atropia, and uses in their stead the yellow oxide of mercury in vaseline, and, in cases of corneal trouble with great lachrymation or secretion, eserin.

Dr. Gustav Zinke, of Cincinnati, next read on the subject of "Quinia-Inhalations in Diphtheria." After speaking of the futile attempts made to treat the disease by the most prized remedies, and the successful termination of many cases when treated by the most simple means, he attributes much of the success in the cases successfully treated by the most simple means to the idea prevailing in the minds of many practitioners as to what constitutes diphtheria. He enters quite largely into the subject of diagnosis, saying that ever since the disease has been first described every writer and teacher has held ideas peculiar to himself concerning the causes and pathology of the disease. Dr. Zinke then accepts the

opinions of Oertel and F. Seitz (Niemeyer), but remarks that their divisions of the disease seem to him as so many stages of the malady, and that it may be confined to one of these or pass on slowly or quickly from the mildest to the most severe. His guides in the diagnosis in the early stage of the disease are, first, a painful throat with febrile excitement; second, a reddened and swollen mucous membrane, marked here and there with distinct fungous growths, or, as he has occasionally observed, with spots that simulate a light application of the nitrate of silver; third, enlargement of the lymphatics of the neck. In looking over the list of remedies, he says there is scarcely one but has had its advocates and its opponents. Only in one respect do all agree, and that is that both local treatment and constitutional treatment are necessary, and that both are apparently of equal importance. Dr. Zinke favors the idea that the disease is merely local in the beginning and afterwards constitutional. After detailing the other methods of treatment that have been employed, Dr. Zinke comes to the conclusion that the only ready method of treatment and the only reliable one is by inhalations of some solution by the atomizer, and for that solution he names quinia as the best agent. Dr. Zinke refers to thirty-five cases reported by him to the Academy of Medicine at Cincinnati, after treatment by this plan, and to seven other cases treated in the same way since the former report, with a mortality altogether of but five per cent. Dr. Zinke seems to use heroic treatment, inasmuch as the solution he advocates is from ten grains to a drachm to the ounce of fluid. A constitutional treatment of aconite and stimulants is also advocated, and as local applications heat or cold, according to the desires of the patient. He emphasizes the importance of the thorough and continued use of the inhalation. He meets the objections to their use in a manner creditable not only to himself, but also to the Society whose influence has called forth the paper.

The only question as to the value of the treatment would remain as to the diagnosis. If it has been correct,—and it seems to be so,—Dr. Zinke deserves credit for his enthusiasm in the treatment.

At the close of Dr. Zinke's paper a vote of thanks was tendered the officials, the press, and the profession of Louisville, for their kind treatment towards the Society, and the meeting adjourned, to meet at St. Louis next year.

Dr. William A. Owen, of Evansville, Ind., was elected President, and Dr. G. W. Burton, of Mitchell, Ind., re-elected Secretary.

PROFESSORS Hofmann, of Berlin, and Kekule, of Bonn, and other chemists, have published analyses of Apollinaris water, which all agree in showing that it is a very pure water, with about one-quarter the quantity of alkaline salts contained in Vichy water.

REVIEWS AND BOOK NOTICES.

THE AMERICAN JOURNAL OF OTOLOGY, A QUARTERLY JOURNAL OF PHYSIOLOGICAL ACOUSTICS AND AURAL SURGERY. Edited by CLARENCE J. BLAKE, M.D., in conjunction with PROFESSOR A. M. MAYER, of Hoboken; ALEXANDER GRAHAM BELL; Dr. ELLIOTT COUES, U.S.A.; PROFESSOR A. E. DOLBEAR, Tufts College, Mass.; Dr. ALBERT H. BUCK, of New York; Dr. CHARLES H. BURNETT, of Philadelphia; Dr. SAMUEL SEXTON, of New York; Dr. J. ORNE GREEN, of Boston; Dr. H. N. SPENCER, of St. Louis. Vol. ii., 1880. New York, William Wood & Co.

When this journal first made its appearance, two years ago, we drew attention to the strong list of contributors, and to the valuable character of both the scientific and the practical papers contained in its earlier numbers. The lapse of time has shown that the high standard originally established has been more than maintained, and the numerous and valuable original articles which have appeared in its pages prove that the journal continues to fulfil the aim with which it set out, to serve not only as the organ of American otologists, but also as at once the purveyor of original and valuable knowledge on the treatment of ear diseases to the general profession, and a medium of expression for writers on scientific matters connected with the organs of hearing, particularly in connection with physiological acoustics. This truly American and scientific periodical is one which is in the highest degree honorable to the profession in this country, and, we are glad to learn, is receiving, at least in some measure, the support which it deserves.

Space prevents our giving more than the most cursory glance at the series of scientific and practical papers spread over the pages before us, but we may mention, among the more notable of the strictly scientific papers, those of Professor Dolbear, "On the Number of Vibrations Necessary for the Recognition of Pitch;" of Alexander Graham Bell, "Experiments relating to Binaural Audition;" and of Charles R. Cross and William T. Miller, "On the Present Condition of Musical Pitch in Boston and Vicinity." Of the numerous practical papers which fill the successive numbers, we may mention Dr. Charles H. Burnett's, on "Uninterrupted Wearing of Cotton Pellets as Artificial Drum-Heads;" and Albert H. Buck's, on "The Comparative Value of Leeches, Heat, and Incisions in the Treatment of Acute Circumscribed Inflammation of the External Auditory Canal." These are just such papers as the intelligent general practitioner reads with interest and advantage. The reviews of current literature are very full and complete.

THE THERAPEUTICS OF GYNÆCOLOGY AND OBSTETRICS. Edited by WILLIAM B. ATKINSON, A.M., M.D., etc. Philadelphia, D. G. Brinton, 1880.

Specialists of extended reputation may covertly sneer at compendiums, each preferring to recommend his own exhaustive treatise; but the hard-worked doctor who lives beyond the hot-house air of our medical centres, where physicians imbibe the latest idea unconsciously with their breath, will thank the editor of this work for placing within easy reach the collated views of many eminent writers, and their special recommendations in therapeutics.

The work is a very valuable member of the series to which it belongs. The editor has acted with great judgment in his labor, and the three hundred and fifty pages can scarcely be read without leaving in the mind many new ideas. Life is growing relatively shorter every year, in relation to the amount of study demanded in all professions and the vast number of books and periodicals that must be read if one would keep afloat upon the topmost wave. A work, therefore, which furnishes a careful digest of various authors, and arranges their views upon various topics together, cannot but save time and prove of great value. E. W. W.

CONTRIBUTIONS TO ORTHOPÆDIC SURGERY, INCLUDING OBSERVATIONS ON THE TREATMENT OF CHRONIC INFLAMMATION OF THE HIP-, KNEE-, AND ANKLE-JOINTS BY A NEW AND SIMPLE METHOD OF EXTENSION, THE PHYSIOLOGICAL METHOD, AND LECTURES ON CLUB-FOOT DELIVERED AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK. By JOSEPH C. HUTCHISON, M.D., Brooklyn. New York, G. P. Putnam's Sons. 12mo, pp. 200.

This handsome volume places in permanent form the articles of the author published already in the *American Journal of the Medical Sciences* and the *New York Medical Record*. The first forty pages contain his views upon the treatment of joint diseases of the lower extremity; and so simple and rational is this "physiological method" that since its promulgation, about two years ago, it has been largely adopted by American surgeons,—at least, with certain modifications. While many will agree with him in the statement that the periarticular muscles are able to fix the hip-joint, yet few will say that it is advisable to compel them to do this work when they can be relieved by the simple use of the same felt which the author employs in treating the knee and ankle, a lock-joint being inserted opposite the hip. Dr. Hutchison's plan consists in lengthening the sound leg some two or three inches by means of a steel, wood, or cork attachment to the shoe, and then putting the patient upon crutches in order to make the diseased member the extending force.

In the lectures upon club-foot the author discusses fully the causes, pathology, and treatment of this unfortunate class of cases. He differs from the majority of American surgeons in that he waits four days after tenotomy before bringing the foot by manipulation into position. His use of plaster of Paris as a retaining-splint after operation is excellent, and saves the expense of a first shoe, while it lessens the risks of sloughing. Page 71, upon the manual treatment of this deformity, is especially worthy of perusal.

The simplicity of the plans of treatment renders the book a valuable one to the general practitioner as well as to the specialist.

DE F. W.

A PRACTICAL TREATISE ON NASAL CATARRH. By BEVERLEY ROBINSON, A.M., M.D. Paris. New York, William Wood & Co., 1880. 8vo, pp. 176.

This book is a carefully-prepared record of the author's views on the causes, symptoms, and treatment of catarrh in the nose and nasal pharynx. The method employed is elaborate, and the conclusions arrived at are stated temperately. The subjects embraced in the contents are coryza, hypertrophy of the turbinated bones, and follicular disease of the naso-pharynx. These affections are separated from one another with more or less success. We cannot cavil over imperfect definitions or rules of diagnosis, however, when the low state of this department of medicine is borne in mind.

It is to be regretted that the classification of the standard writers is often departed from without explanation; for example, that ulcerous catarrh is frequently alluded to without being anywhere distinctly defined, and that ozæna is not mentioned as a nasal disease, while the author has not hesitated to use the word in his discussions. It would further assist the reader if the paragraphs were shorter and the references to the writers quoted had been more uniform. But these are slight defects, and will not interfere with the usefulness of the volume. It is enough for the practitioner to remember that he can find in Dr. Robinson's volume a reliable guide in the treatment of a group of obstinate disorders.

H. A.

ARCHIVES OF OTOLOGY. Vol. ix., No. 3. New York, G. P. Putnam's Sons, September, 1880.

The most interesting papers in this number are those of Gottstein and Guye, upon Ménière's disease. Defining this disease as an affection of the internal ear associated with vertigo, the practical question arises, Is the vertigo a primary or a secondary symptom? This query suggests a second, viz.,—How can the vertigo of Ménière's disease be distinguished from vertigo having its cause in other structures than the labyrinth?

Gottstein finds two groups of cases in which deafness and disturbances of equilibrium are united. One of these he assigns entirely to meningeal origin, the deafness being an associated symptom thereof. In another the deafness and vertigo appeared simultaneously and distinct from meningeal symptoms.

Guye brings together a number of cases of disease of the middle ear in which the vertigo and a variety of symptoms referrible to the central nervous system supervened as complications. He notes, as important points, that the sensations of rotation are invariably towards the affected ear; that a current of cold air or the direct contact of cold water upon the affected ear is peculiarly noxious; and, finally, that the patient is not apt to suspect his ear as being in any way connected with his disease.

Dr. F. C. Hotz narrates three interesting cases in which acute purulent otitis was thought to be dependent upon malarial poisoning.

A Manual of Medical Jurisprudence. By Alfred Swaine Taylor, M.D. Eighth American from the Tenth London Edition. Containing the Author's latest Notes made expressly for this Edition. Edited by John J. Reese, M.D. Philadelphia, H. C. Lea.

It is not very often that a medical book reaches its tenth edition, or that the last earthly labor is performed by the author in retouching the work that first came from his hand thirty-five years before. All this, however, has happened in the case of Dr. Taylor and his classical treatise. The pen dropped from the grasp only when the shadows of old age were rapidly deepening into the darkness of death. Under the circumstances, all the journalist has to do is to announce, not criticise, the completed task. The value of the gem is too well known to require more than the telling that the master-hand has rebrightened its facets and polished its angles before leaving it as his legacy to his brethren in the profession.

Descriptive Atlas of Anatomy. Philadelphia, J. B. Lippincott & Co.

This royal quarto volume is composed of ninety-two plates, containing five hundred and fifty figures, a preface of two pages, and an index of eleven pages. The Atlas is intended chiefly for the use of students, and has been prepared by a London hospital surgeon, whose name graces neither title-page nor preface. Is he ashamed of his work? After examination we do not find that he has any cause to be, except those plates illustrating the brain, where the old, stale, flat, and unprofitable figures and methods of Gray and other text-books are reproduced; but then it would be a rare surgical intellect which would rise to the comprehension and knowledge of brain anatomy as required by the physiologist and neurologist. The drawing of the figures is by no means fine, but it is bold and strong, and the arteries and veins are appropriately colored, which brings a strong relief. As all parts of the figures are copiously named *in situ*, it can be seen that the volume offers great facilities for refreshing of the memory and for coaching. We have met with some practitioners as well as students to whom anatomy partook of the nature of a lost knowledge, if not of a lost art. To such the present volume would be very useful. The most extraordinary thing about the work is its cheapness, the full retail price being only $7.50. With the usual discount off, this would be about one cent a figure, —a color—if not blood—stained figure at that. Unsigned paintings, unwarranted auction-horses, and anonymous scientific books belong to classes which the wise man views with deep distrust; but the present volume hides no secrets. Its face-value is all it has, and to take this at the price at which it is offered is to embrace a bargain.

GLEANINGS FROM EXCHANGES.

Case of Imperforate Rectum—New Treatment.—Dr. Neil Macleod's case (*Brit. Med. Jour.*, vol. ii., 1880, p. 657) was that of a female infant in whom, the bowels not having been moved twenty-four hours after birth, a probe was passed into the anus, which was found to communicate with a *cul-de-sac* about half an inch in depth. The probe was then passed into the vagina for nearly two inches. It could be moved about with freedom, and could be felt readily from the anal *cul-de-sac*, where the rectum should have been. There was no bulging in the perineum.

A perineal exploration was made for the rectum, the operator cutting carefully in the middle line to the depth of an inch and a quarter without being able to feel with the finger anything like a bulging, loaded bowel. Littré's operation was performed, some hemorrhage ensued from abdominal vessels, and death took place nine hours later. The necropsy showed the peritoneal cavity perfectly free from any trace of inflammation, blood, or meconium. The perineal wound did not communicate with the peritoneal cavity. The rectum was completely imperforate, being represented by a slender, impervious, fibrous cord, running down from the descending colon, almost in the middle line, into the pelvis behind the uterus, and attaching itself to the posterior wall of the vagina opposite the os uteri. It could be traced for three-quarters of an inch along the posterior vaginal wall, where it spread out and became lost thereon. The descending colon ended in a *cul-de-sac* at the pelvic brim, greatly distended, being about three times the diameter of the colon three or four inches higher up. The va-

gina was long and roomy, and had very thick walls. The cervical portion of the uterus had a diameter twice that of the fundus uteri. The bony pelvis was normal. In his remarks on the case, Dr. Macleod says that the objections to Littré's operation are: hemorrhage, opening the bowel in the wound, leading to the risk of the escape of meconium and blood into the peritoneal cavity, and the very grave one, if the patient live, of having an artificial anus in the groin. He suggests that when the ano-perineal operation fails to reveal the bowel an incision should be made in the abdominal wall of convenient length between the umbilicus and pubes in the middle line (or a little to the left of it, to avoid the urachus and the hypogastric artery). Next, he says, introduce the forefinger of the left hand into the abdominal cavity, examine the descending colon and rectum to discover the seat and relations of the upper *cul-de-sac*, then pass the same finger down into the pelvis in the middle line (behind the uterus in the female, the bladder in the male), and, pressing the tip of the finger against and pushing outwards the floor of the pelvis, cut upon the tip of the finger as a guide, thus opening into the peritoneal cavity from below. Next introduce the right forefinger through the perineum, and, guided and assisted by the left, hook the right finger round the gut, and pull it downwards and out through the perineal incision. Stitch the opening in the abdominal wall, then open the gut and stitch its edges to the edges of the perineal wound in the manner before described. Should the difficulty arise, from mesenteric relations, of bringing the bowel down from the pelvic brim (only in the worst cases) to the perineum, the mesentery could be torn or cut through and vessels tied. Whatever the nature or degree of malformation, the rectum on the right side, partially or completely imperforate, opening into the uterus, vagina, bladder, or urethra, by the means suggested (failing the ano-perineal operation) the condition could be more properly ascertained and dealt with. In some cases the peritoneal cavity need not be opened from below. Antiseptic precautions should be employed.

Blood-Poisoning.—A singular case of blood-poisoning occurred at Berne recently. A man, who for several days was suffering from toothache, went to a dentist, who advised him to apply a leech to the gums. The man did as he was ordered, but two hours afterwards he found himself worse, and remarked that his lips were commencing to swell, and soon this swelling extended to the face, neck, and chest. He waited until the following day to call in a doctor, but by that time the whole head became involved, the respiration became difficult, and high fever set in. A few hours later the patient became delirious, and was seized with convulsive movements; he appeared at times to sleep with the eyes open. On the second day he succumbed. Professor Langhans, having made the post-mortem in the presence of two other well-known professors, declared it to be a case of blood-poisoning. The wound produced on the gums by the leech had enlarged itself, showing gangrenous edges. It is evident that this bite had transmitted a virus, which had thus poisoned the blood. But how this virus could have been introduced into the leech, which had been in the chemist's shop for several days, could not be ascertained.—*Medical Press and Circular.*

How to Cover the Odor of Iodoform.—Several methods have been proposed, the following of which, according to *New Remedies*, are the best. 1. Tannin mixed with the iodoform in equal parts. 2. Oil of peppermint in the proportion of a drop to every drachm. 3. Lavender water and eau de cologne have been recommended, but are not so effectual as the peppermint. 4. Balsam of Peru, 3 parts; iodoform, 1 part; vaseline, 8 parts; or, in place of the latter, alcohol, collodion, or even glycerin. 5. Oil of sweet almonds added in equal quantity to the iodoform. 6. Oil of bitter almonds. One or other of the first two methods is probably to be preferred.—*British Medical Journal*, vol. ii., 1880, p. 692.

Death from Ether.—Dr. N. C. Dandridge reports a death from ether. A full account of the case, which was discussed by the Cincinnati Medical Society, will be found in the *Cincinnati Lancet and Clinic* for October 30.

MISCELLANY.

Pure Water in Cities.—We are told upon high authority (Dr. Henry I. Bowditch) that "only one-third of the towns and cities of this nation make any claims, even the most trivial, of endeavoring to procure pure potable water for their inhabitants. The remainder (65.73 per cent.) either confess carelessness or ignorance of the subject. In other words, over one-half of the people of these United States are openly and avowedly living in a senseless disregard as to whether they are drinking pure water or water contaminated by every kind of filth."

Popular Physiology.—It appears that under the new "scientific" influences children in the London Board Schools are taught physiology. An examiner having put the question, "Mention any occupations which you consider to be injurious to health, giving reasons for your answer," one girl's complete answer to this was, "When you have a illness it makes your health bad, as well as having a disease." Another said, "Occupations which are injurious to health are carbolic acid gas, which is impure blood." Another complete answer was, "We ought to go in the

country for a few weeks to take plenty of fresh air to make us healthy and strong every year." Another complete answer was, "Why the heart, lungs, blood, which is very dangerous." The word "function" was also a great puzzle. Very many answered that the skin discharges a function called perspiration. One girl said, "The function of the heart is between the lungs." Another said, in answer to "What is the function of the heart?" "Thorax." Another girl, in answer to a question, said, "The process of digestion is: we should never eat fat, because the food does not digest."

PREVALENCE OF ADULTERATION OF FOOD.—The recent report of the State Board of Health, Lunacy, and Charity of Massachusetts (*Sanitarian*, November, 1880, p. 511) contains a paper by Mrs. Ellen Richards, Instructor in Chemistry in the Woman's Laboratory, on the "Adulterations of Some Staple Groceries," which shows a gratifying result. Of 25 samples of flour and 75 of sugar there were no adulterants whatever discovered. One sample of sugar only indicated glucose in a faint degree.

Of soda, the so-called "saleratus, bicarbonate, or super-carbonate, cooking-soda," all being names for one and the same thing, 93 samples were examined: 19 were nearly chemically pure, 43 were good, 25 contained from three to sixteen per cent. of chloride and sulphate of sodium, but of these 25 three only were bad. Alum was not found in a single sample. Seven packages were found without the name of the manufacturer, only the names of the mills being given. Every one of these was adulterated; one was largely flour, the other six contained over fifty per cent. of terra-alba. One other package had the maker's name, but no place of business, on the label, and contained eighty-one per cent. of terra-alba. Two packages were labelled simply "Horsford's Cream of Tartar," and consisted of acid phosphate of lime.

Of baking-powders, 33 samples were tested: 24 were good, containing nothing injurious; some of them contained an excess of starch or flour. Of the remaining nine, eight contained alum, and five of these last also contained ammonia.

PILOCARPIN AND JABORIN.—Drs. Harnach and Meyer (*Annalen der Chemie*) have examined the chemical and pharmacological properties of commercial pilocarpin, and the result of their researches has led them to the conclusion that a new alkaloid, which in lieu of a better name they have called "jaborin," is contained, together with pilocarpin, in the pilocarpin of commerce, jaborin being, in fact, formed out of pilocarpin. According to the authors, pilocarpin is, in its physiological effects, analogous to nicotine, while the effects of jaborin they found to be identical with those of atropin. The separation of jaborin and pilocarpin is based upon their different degrees of solubility in various menstrua, the separation being facilitated by the non-crystallizable property of the jaborin compounds. The presence of jaborin in commercial pilocarpin was indicated by the action of the latter upon a frog, traces of jaborin causing spasms of the heart. Pure pilocarpin the authors found to contain no jaborin. After having, by means of its physiological effects, determined the presence of jaborin in commercial pilocarpin, the authors set to work to prepare it in at least sufficient quantity to enable them to experiment upon it. The raw materials selected for this purpose consisted in part of jaborandi leaves and in part of the so-called false jaborandi, piper reticulatum, and other kinds of pepper. Not having been able to obtain jaborin in a state of perfect purity, the authors have not been at present able to represent it by a formula. Jaborin is a very strong base, differing from pilocarpin by being with difficulty soluble in water and easily soluble in ether. Its salts dissolve readily in water and alcohol, and are not crystallizable.—*Medical Press and Circular.*

FALLING OF THE HAIR.—Mr. James Startin, in the *British Medical Journal*, suggests the following application in general loss of hair without obvious cause:

℞ Ung. petrolei,
Ol. ricini, āā ℥ss;
Hyd. ox. rub., gr. v;
Liq. ammon. fort., f℥ss;
Ol. rosmarini, gtt. v.—M.

ALCOHOL AND DIGESTION.—M. Leven (*Boston Jour. of Chemistry*) claims that seventy-five grammes of brandy to two hundred grammes of meat completely arrest digestion, while twenty-five grammes in the same quantity facilitate digestion. Dr. Rabuteau finds ethylic alcohol far less injurious than amylic.

NOTES AND QUERIES.

ERRATUM.

IN the analysis of the Kittanning Spring-Water (p. 77), by Dr. Reichert, for salicylic acid read *silicic acid*.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM NOVEMBER 14 TO NOVEMBER 27, 1880.

TAYLOR, M. K., CAPTAIN AND ASSISTANT-SURGEON.—To report to Commanding General, Department of the East, for assignment to duty. S. O. 242, A. G. O., November 12, 1880. Assigned to duty at Fort Wayne, Mich. S. O. 204, Department of the East, November 17, 1880.

HOFF, J. V. R., CAPTAIN AND ASSISTANT-SURGEON, Fort Monroe, Va.—Granted leave of absence for one month. S. O. 208, Department of the East, November 26, 1880.

TESSON, L. S., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for six months, with permission to go beyond sea. S. O. 244, A. G. O., November 15, 1880.

BREWER, J. W., CAPTAIN AND ASSISTANT-SURGEON.—Died November 15, 1880.

PHILADELPHIA, DECEMBER 18, 1880.

ORIGINAL COMMUNICATIONS.

WINTER HEALTH-RESORTS—THE CLIMATE OF ATLANTIC CITY, AND ITS EFFECTS ON PULMONARY DISEASES.

BY BOARDMAN REED, M.D.,
Atlantic City, N.J.

WHERE shall we send our invalids for a change of air in winter? This is a practical question which is becoming, year by year, more important to busy physicians, particularly in the great cities of the North. There are certain chronic diseases for which a pure and invigorating air, and especially a climate which will tempt the patients out of doors, are highly desirable. For many cases a change to such an air offers the best hope of cure, or even of amelioration.

Florida has been much in vogue lately as a winter-resort, and undoubtedly suits numerous patients well; but it is too far away, involving a long and tiresome journey. The distance from home and friends, and the impossibility of conferring in an emergency with the usual medical attendant, are serious inconveniences. The prevalence of malaria there is a source of danger, and the very warm and enervating character of the Southern climate unfits it for a large class of diseases altogether.

Colorada and Minnesota are even farther away, and their climates, however tonic and useful, are so cold that invalids there can live very little out of doors during the winter; and if they are to be kept prisoners in close heated rooms it might almost as well be in their own homes.

Northern Africa and Southern Europe, especially Pau, Nice, Mentone, and other places along the northern shore of the Mediterranean, are just now in great repute. Invalids are flocking thither every winter, and, the impartial chroniclers tell us, are leaving their bones in the cemeteries there in sadly large numbers.

Dr. Madden, in his "Health-Resorts of Europe and Africa," says, "With one exception the most frequented winter health-resort in Europe is Pau;" then proceeds to denounce the climate as "essentially cold, variable, damp, and dreary during the winter." During one December while he was there he states that "the thermometer *fell eleven times to zero.*"

Dr. John Parkin, in his work on "Climate and Phthisis," is equally emphatic in condemning that climate, saying, among other things, that "of a number of patients I have known who passed a winter in Pau, not one received any benefit,—the majority died soon after their return.

As to Nice and Mentone, Dr. Madden quotes several medical travellers and former resident physicians to the effect that these places are exposed to very sudden changes of temperature, and that the native residents are very subject to pulmonary complaints, which with them are apt to run a rapid course. Dr. Parkin, in the work already quoted, is particularly severe upon the climate of those places, stating that though it is usually very warm there in the sun, insomuch that umbrellas are indispensable, it is apt to be cold in the shade, necessitating the heaviest wraps. Crossing the street is like passing from summer to winter. The same author shows that, from the location of these towns in the neighborhood of mountains, some of whose tops are always covered with snow in winter, they must be continually subject to cold, raw winds, which are all the more intolerable and dangerous because of the heated air which they displace.

Says Dr. Parkin, "During January and February, then, there would be two cold winds prevailing at Mentone, as is frequently the case at Nice. It is not surprising, therefore, that I should have left the latter town in the month of March in a snow-storm, or that snow should have fallen heavily all the way to Genoa."

Dr. J. H. Bennett, of Mentone, the chief eulogist of that climate, insists very strenuously upon certain precautions against taking cold. "Without them," he says, "it is unsafe and treacherous. This is evidenced by the great mortality of the natives of the Nice and Mentone districts by pneumonia and pleurisy, two of the commonest maladies."

Dr. Parkin's conclusion is that the *Riviera* is "one of the most unfavorable and dangerous climates for chronic diseases of the respiratory organs, and especially for phthisis." As to Africa, he cites army reports showing that "of the British troops

passing through Egypt during 1872 *en route* for India, 29.9 per 1000 were attacked with phthisis and 2.3 per 1000 died." He adds, "When it is remembered that these patients manifested no symptoms of the disease when they left England, otherwise they would have been detained, this result speaks trumpet-tongued as regards the influence of such a climate in the development of phthisis."

If these are the most desirable winter-resorts in the Old World, American invalids, especially those suffering from chronic pulmonary affections, would do well to remain on this side of the ocean.

Atlantic City, New Jersey, a place most favorably located as regards convenience of access, being less than two hours' ride from Philadelphia by any one of three railroads, and only four hours from New York by the Pennsylvania Railroad and its West Jersey branch line, possesses certain physical advantages which are well worth considering. It has been twenty years or more since physicians began sending patients here in winter. First only now and then a courageous invalid ventured here at this season, but their numbers steadily increased. The experiment proved so successful in hastening the convalescence from acute disease, in improving a large class of chronic affections, and especially in arresting numerous cases of incipient as well as confirmed consumption, that within the last three years the travel to the place in winter has reached very considerable proportions, and the numerous thoroughly heated winter hotels—some of which are as sumptuously furnished and as luxuriously conducted as the leading houses at the summer-resorts — are crowded with invalids, convalescents, and wearied society people through all the months from January on.

Actual experience has demonstrated that sea air is as valuable in winter as in summer. It also bears out the statistics which prove that the climate of Atlantic City is superior to that of most sea-coast towns, being drier, more equable, and, considering the latitude, unusually mild.

The city—for it is in fact as well as in name a city, having a permanent population of six thousand, and being supplied with gas, street-cars, etc.—is situated in latitude 39° 22′, on an island ten miles long and averaging about half a mile wide. This is separated from the mainland at either end by broad bays or inlets, which are connected by a narrow arm of the sea called "The Thoroughfare." There is no body of fresh water nearer than the Delaware River, distant about sixty miles, and the salt-water bays to the landward side are nearly always open, ice seldom forming, except for a short time occasionally in the severest winters.

Another peculiarity of the location is that all the winds from the landward must pass for long distances—hundreds of miles in some directions—over a very dry and porous sandy soil upon which snow rarely lies for any time. These winds, including those from the north, northwest, west, and southwest, are therefore to some extent both dried and warmed in their passage.

Though the coast of Southern New Jersey has a general direction from northeast to southwest, the beach at Atlantic City trends more to the westward, so that it faces almost directly southward. Therefore south as well as east winds are sea-breezes here, and both blow across the Gulf Stream, which, by the way, exercises considerable influence upon the climate of this part of the coast.

Mr. C. P. Patterson, Superintendent of the United States Coast and Geodetic Survey Office at Washington, has kindly furnished me with a large map indicating accurately the course of the Gulf Stream, and with some interesting facts concerning it.

This map shows at a glance that the heated waters of the tropics, pouring through the space between Cuba and Florida, flow in a northeasterly direction along the coast of Georgia and the Carolinas, diffusing themselves as they go, until from a compact stream less than fifty miles wide, they have become opposite Chesapeake Bay a broad expanse upwards of four hundred miles in width. This really includes numerous parallel or slightly diverging currents of very warm water with overflow currents of a somewhat lower temperature. One of these overflow currents approaches within sixty-five miles of Atlantic City, while it is one hundred and ten miles from Sandy Hook. The principal current is farther away, being one hundred and thirty-five miles from Atlantic City, one hundred and eighty-five miles from Sandy Hook, and about the same distance from Long Branch and Montauk Point.

But the exceptional mildness of this

climate may be attributed to the peculiar course of the Gulf Stream in this vicinity as much as to its proximity. The innermost current, according to the map received from the Coast Survey Office, has a direction opposite Atlantic City of east-northeast, but turns more and more to the eastward till in latitude 40°—that of Philadelphia—it bears nearly due east. The main current turns more abruptly, and a little north of latitude 38°, some distance to the southward of Atlantic City, has a course directly eastward. Our south, southeast, and east winds, then, must all pass for three hundred to five hundred miles at least over more or less heated water which has come directly from the Gulf of Mexico. Our only ocean breezes not affected in this way are those from the northeast, and experience shows that these are the only winds which are generally unpleasant here. But for places farther up the coast, particularly those north of latitude 40°, the case is different. Neither their northeast nor east winds can be appreciably modified by the Gulf Stream. Their south and southeast winds may be favorably influenced to some extent, but less than are the same winds at Atlantic City, since they pass over a much larger surface of cold water after crossing the Gulf Stream. It may be added that some small maps issued by the Signal Service Office represent the Gulf Stream as occupying different positions in winter and summer, but on this point Mr. Patterson writes, "I greatly doubt if there can be any material change of the stream from season to season; at least there has been no reliable evidence obtained on that subject."

To Sergeant E. W. McGann, who has charge of the United States Signal Station at Atlantic City, I am indebted for meteorological statistics and official records, from which the following information, bearing directly upon the subject of the climate of the place, has been condensed and tabulated:

TEMPERATURE, HUMIDITY, BAROMETRICAL PRESSURE, AND RAIN-FALL AT ATLANTIC CITY, NEW JERSEY.

Months, 1880.	Mean temperature.	Range of temperature.		Mean humidity.	Mean barometer.	Rain-fall, in inches.
		Max.	Min.			
January	41.1	64	13	79.3	30.189	1.70
February	38.2	71	11	74.4	30.129	2.85
March	40.1	72	18	71.9	30.061	5.97
Mean for three months..	39.8	.....		75.2	30.126	10.52

The mean temperature for January, February, March, and December, the four coldest months of the year, was, in 1879, 34.7°; in 1878, 36.8°; and in 1877, 35.9°.

The prevailing winds in winter are those from the west and northwest, which are usually dry and bracing. The east and south winds, which often blow for days at a time, are warmer and more humid. Northeast winds, which are unpleasant, usually prevail for two or three days at the time of the equinoctial storms, but are infrequent during the remainder of the year.

Observations taken at my office, in the centre of the town, at 7 A.M., 12 M., and 6 and 10 P.M., show that in December, 1879, there were twenty-six days during which the thermometer did not fall below 32°,—the freezing-point; also that there were only two days in the same month when the thermometer did not indicate at noon a temperature above 40°; and that there were ten days upon which it was not below 50° at the same hour. During the January following (1880) there were twenty-four days during which the mercury never fell below the freezing-point at any hour, and only two days during which it went below 30°. It was only once in the same month lower than 40° at noon, and only three times lower than 45° at the same hour. On nineteen of the thirty-one days the thermometer stood at 50° or above at mid-day.

These mid-day temperatures are obviously more important than averages, for it is in the daytime that invalids take their airing out of doors.

The dryness of this climate, as compared with other sea-side resorts, is best

shown by the statistics of the rain-fall, which is less here than at any other place on the coast, as appears from the table given below. The readings of the hygrometers at the different stations are not so significant, since at some of them, including Atlantic City, the instruments are located so near to the beach, and at so low an elevation above the sea-level (less than thirteen feet here), as to be affected by the spray, during strong winds, off the water, and by occasional morning mists, which do not extend back into the town.

ANNUAL AMOUNT OF RAIN-FALL AT THE PRINCIPAL CITIES AND STATIONS ON THE ATLANTIC COAST.

Stations.	Year ended June 30, 1879.	Year ended June 30, 1878.
Atlantic City, N.J.	40.60 inches.	42.90 inches.
Barnegat, N.J.	49.38 "	52.35 "
Boston, Mass.	62.96 "	54.50 "
Cape May, N.J.	42.44 "	47.99 "
Charleston, S.C.	64.33 "	68.62 "
Galveston, Texas	51.03 "	67.47 "
Jacksonville, Fla.	51.62 "	52.11 "
Newport, R.I.	52.20 "	55.84 "
New Orleans, La.	58.29 "	73.31 "
New York, N.Y.	43.68 "	42.68 "
Norfolk, Va.	44 44 "	66.28 "
Portland, Me.	41.10 "	45.61 "
Sandy Hook, N.J.	60.37 "	54.86 "
Savannah, Ga.	55.14 "	52.44 "
Wilmington, N.C.	50.90 "	84.12 "

The mean barometer for the year ended June 30, 1879, was higher at the Atlantic City station than at any other on the coast north of Chesapeake Bay, and, with one or two exceptions, the same may be said as to the preceding year. This is a matter of importance, since depressions of the barometer affect the majority of invalids far more decidedly and injuriously than low temperatures. An extra wrap out of doors or a fire in-doors will perfectly antidote any ordinary degree of cold, but it is far more difficult to render comfortable the invalid whose breathing is distressed or whose joints and nerves have been set to aching by a sudden fall in the atmospheric pressure. Barometrical changes are also connected intimately with variations in the electrical conditions of the atmosphere, and these again strongly impress the delicate nervous systems of the sick.

In the following table the figures represent the average atmospheric pressure for the years named *at the sea-level*, allowances having been made for differences in the elevation of the stations:

TABLE SHOWING MEAN BAROMETER AT VARIOUS STATIONS.

Stations.	Year ended June 30, 1879.	Year ended June 30, 1878.
Atlantic City	30.031	30.002
Barnegat	30.029	29.998
Boston	29.975	29.969
Cape May	30.029	30.007
Galveston	30.049	29.995
Jacksonville	30.079	30.030
Newport	29.993	29.980
New York	30.026	30.006
Portland, Me.	29.944	29.952
Sandy Hook	30.014	30.000

After all, however, it is with climates as with medicines,—trustworthy evidence as to what they have accomplished is the most valuable. With regard to nervous, rheumatic, gouty, dyspeptic, and various other chronic ailments (including most of those peculiar to women), which are usually found to be benefited here in the summer, equal benefit may be expected in the winter. Convalescents from acute disease, or from surgical operations, nearly always improve remarkably upon being removed to this place from the large cities.

As to diseases of the respiratory organs, I have had personal knowledge of many patients suffering from all the forms of such affections who have made trials of this climate in winter. The bronchial and laryngeal cases have, as a rule, improved, some of them very decidedly, though there have been exceptions. The consumptives who were in the third stage, or in any stage with evidences of actively progressing disease of the lung and decided hectic, have only exceptionally been benefited. Those, however, in the pretubercular or incipient stage, and those even in the advanced stages where the destructive process has been advancing slowly, have often experienced very marked improvement. In a considerable proportion, about one-fourth, of these latter classes of cases the disease has been apparently arrested, and some of them seem to be cured.

Detailed reports of the cases I have treated at Atlantic City would fully bear out the foregoing general conclusions, but would unduly extend this paper and necessitate the exclusion of several reports I have received from prominent Philadelphia physicians concerning the effect of this climate upon their patients in winter especially. Some of these physicians have been sending patients hither for more than

twenty years. Their testimony is more valuable than mine, and cannot be impugned on the ground of partiality.

It is a significant fact that pneumonia and bronchitis are of infrequent origin here, and when they do occur the patients *almost invariably recover*. Upon this point my experience as a resident physician enables me to speak very positively. I have not known an uncomplicated attack of either disease to prove fatal.

The reports from physicians above referred to were received in response to inquiries recently sent to them. Many others wrote brief apologies, not having the notes or the leisure to tabulate the results of their experience as I had requested. Only one physician objected to the climate either for bronchitis or early phthisis.

Dr. Laurence Turnbull writes, "The number of cases of phthisis that I have sent to Atlantic City have been few *in the last stages*, as I found they were not improved by a residence at the sea-shore, dry even as it is," adding that a few cases in those stages were aggravated, but goes on to say, "I have been much pleased with its influence on the first stages of phthisis, asthma, laryngitis, bronchitis, and nasal catarrh, when all ordinary means have failed in the city, by causing improvement in the appetite, assisting the digestion, and giving a healthier tone to the skin. In convalescence from catarrhal pneumonia and typhoid fever the results have been most gratifying. In certain forms of *otitis media purulenta* I do *not* find the air of Atlantic very beneficial, and in many cases diseases of the ear are caused by exposure of that organ to the waves. In strumous diseases of eyes, joints, limbs, etc., I have found the change to Atlantic City, if persisted in for several seasons, of permanent benefit."

Dr. Thomas J. Yarrow writes, "It has not been my practice, as a rule, to advise patients suffering with tuberculous and other diseases of the respiratory passages to sojourn at the sea-side. Exceptionally, I have had them go to Atlantic City, and have known cases of incipient phthisis, chronic bronchitis, asthma, and laryngitis to improve in that location. My experience of late is inducing me to recommend a larger number of such cases to reside at Atlantic City."

Dr. Thomas G. Morton thus bears testimony: "I have been in the habit of sending to the shore at Atlantic City many patients, more especially surgical cases, but a large number also of those with lung affections, and especially those having a (hereditary) tubercular disposition, and I think especially such cases have been vastly benefited by the sojourn."

Dr. James Darrach, of Germantown, writes, "Have sent several cases of autumnal catarrh to Atlantic City, and think without exception they were benefited, two of them being certainly exempt from these attacks while at the shore. The only case of slow convalescence from pneumonia died at Atlantic City. This was about twenty-three years ago. A case of obstinate general bronchitis was cured in about ten days. A case of what I supposed to be tubercular laryngitis was very much benefited, and subsequently recovered. I have also had other cases of obstinate catarrh which returned well after a sojourn at Atlantic City."

Dr. Eugene P. Bernardy reports as follows: "With but one exception, all my cases of phthisis, both in the early and late stages, amounting to twelve in all, have been decidedly benefited by a sojourn at Atlantic City, and one case positively cured,—that is, as far as human ear can ascertain. Of the three cases of convalescence from pneumonia all were decidedly benefited. In a child suffering from chronic pneumonia the lung in a few weeks was almost entirely cleared up. In bronchial affections (chronic) I have seen no permanent benefit in any of the six cases I have sent there: all benefited while at the sea-shore, but a few months after their return relapsed. The case of phthisis cured had been examined by myself and Dr. Hall in Philadelphia, and while at the sea-shore examined by Dr. L. Turnbull. We all diagnosed incipient phthisis. This was nearly six years ago. On her return she had gained forty pounds, and has remained well ever since."

Dr. John H. Packard says, referring to Atlantic City, "I can only say that I frequently advise convalescents to go there, and that it is a very common thing with me to be asked by patients whether it would not do them good to spend a week or two there. I do not now recollect any case that has been wholly without benefit from that climate, and could adduce many that have gained great advantage from it."

Dr. D. Murray Cheston writes, "I can-

not say how many cases of pulmonary or bronchial troubles I have sent there, but the general result has been most satisfactory. The cases were all sent in the late winter or early spring months, and have invariably returned improved."

Prof. J. M. Da Costa writes briefly, as follows: "I have sent too few patients with pulmonary disease to Atlantic City to have the data to answer your questions. Some who were in a run-down condition and affected with chronic bronchial catarrh did very well."

Dr. Ellwood Wilson writes that in the summer months he does not think patients with fully-developed phthisis improve by a protracted residence at Atlantic City, but adds, "During the winter months—say from October to July—I regard it as a very favorable locality for consumptive patients."

Dr. R. J. Levis writes that his practice (being almost exclusively surgical) "is not of a kind to furnish experience with regard to the beneficial influence of Atlantic City in pulmonary affections," but that he has "a good opinion of its dry and mild climate."

Dr. James J. Levick has not sent any cases of phthisis, but has sent "several cases of laryngeal and bronchial irritation and one or two cases of hay asthma, which improved greatly while at Atlantic City." He adds, "The cases which have derived most benefit, however, and of which I have sent not a few in the late winter months, have been patients after typhoid fever,—patients whose nervous systems have been much disturbed, persons who have needed brain rest, etc."

Dr. Wm. H. Bennett, resident physician at the Children's Sea-shore House and Seaside House for Invalid Women at Atlantic City, contributes the following full report: "My experience of the effects of a sojourn at Atlantic City upon those suffering from pulmonary diseases has been confined to what I have seen among transient visitors during the summer months of the past seven years. I have had little or no experience of the effects either of a prolonged stay or of a stay in winter. I cannot give you exact figures, but the following is a fair statement of what I have observed. My patients were, with the exception of a majority of those suffering from phthisis, nearly all children. I have had not less than a hundred cases of acute bronchitis, nearly all of which ran a milder and shorter course than similar cases do in Philadelphia. The majority of these cases had during treatment the best possible hygienic surroundings, but a few which were much exposed during cool, rainy weather in leaky, damp apartments seemed to do equally well. A few, perhaps ten, cases of subacute bronchitis which had remained stationary in the city for some time rapidly recovered at the sea-shore. Three or four cases of chronic bronchitis, with emphysema and occasional severe attacks of asthma, greatly improved; but about an equal number showed no change. Two or three cases of tardy convalescence from pneumonia made much more rapid progress towards recovery after their removal to the sea-shore. Two cases of empyema with external fistulæ greatly improved. About twenty cases of phthisis have been under my care at Atlantic City. These have been in all stages of the disease. A very few, I recall but three, derived no benefit; all the others improved in general health. In some, even of the advanced cases, the improvement was marked. In many of the cases the cough became less troublesome and the breathing less labored. Nearly all slept better. Hectic frequently disappeared entirely, or was greatly lessened. These cases, with two exceptions, remained too short a time to allow of any inference in regard to the effect of their stay upon the progress of the disease itself. One of these two exceptional cases remained three months. It was one of the few that did not improve at all, and the disease ran its usual course. The other spent most of the time during the last eighteen months of his life at Atlantic City, and his downward progress was undoubtedly much retarded by so doing. I am aware that the experience which I have thus detailed has been too meagre, except perhaps in the cases of acute bronchitis, to allow of any general conclusions. But, after comparing my own experience with that of others, I am convinced that the atmosphere of Atlantic City in summer (perhaps also in winter, but I do not know) will prove especially beneficial in the large majority of cases of diseases of the respiratory organs, and that the very common opinion that the seacoast is everywhere unsuitable for cases of phthisis has little foundation. So thoroughly am I convinced of this fact that I

am striving to have special provision made in the Sea-side House for Invalid Women for consumptives, and in doing so I am but following in a small way the example set by the establishment of the magnificent Royal National Hospital for Consumption on the sea-coast of the Isle of Wight."

The good accomplished by this climate I attribute not to any specific influence of the air upon the lungs, but to its tonic and alterative properties, acting by the improvement of digestion and nutrition, the promotion of sleep, etc. Atlantic City is the most accessible to the New England and Middle States of any place having claims as a winter-resort and admitting of outdoor exercise for most invalids the whole winter through.

TWO EXAMPLES OF PURPURA HÆMORRHAGICA FROM WIDELY DIFFERENT PRIMARY CAUSES.

BY WALTER C. STILLWELL, M.D.

CHAS. H., æt. 8, while playing in a stable-yard was incarcerated in a dung-pit by his playmates for about twenty minutes to half an hour, and a few hours after being liberated he was seized with a chill, followed by the appearance of red spots over the whole body, which gradually became of a purple color, and soon after he began to have hemorrhage from the nose, which was very profuse and lasted for some considerable time; he became exceedingly weak, his pulse grew feeble and very rapid, and for a time his condition was very alarming. On making an examination of his throat, I found the tonsils so much enlarged that they almost filled up the fauces; they were of a dark-purple color, and looked as if the blood was about to start from them. The other portion of the mucous membrane of the mouth and throat was very pale and unnatural in color.

Attention was first directed to stopping the hemorrhage, which was done after much difficulty; the various vegetable and mineral astringents were used without effect, and, as a last resort, I was compelled to plug the nostrils with cotton saturated with a strong solution of alum.

The tinct. ferri chlor. with potass. chlorat. in large doses was administered internally, in conjunction with strong milk-punch. This treatment was continued for about five days, when the sulphate of quinia was added to the other medicinal agents. A week or ten days passed before I considered him in a fit condition to leave.

The other case was that of a little girl, 9 years of age, who was a typhoid fever patient, the purpuric spots appearing about the tenth day of the attack, accompanied by a profuse bleeding from the nose, as in the other case, and after a day or two cerebral symptoms set in and the child died.

Here are two cases of purpura hæmorrhagica, with the extravasation of blood in or upon the true skin, appearing in spots over the whole body: both are caused by a depraved or poisoned state of the blood and the relaxed condition of the capillary vessels.

In the first case, the child inhaled the ammoniacal and other putrescent vapors from the refuse matters in the pit, and the inoculation or absorption of the poison was through the respiratory apparatus; but in the second case, the typhoid fever patient, it occurred through the medium of the bowels, the matters from the diseased glands of Peyer being absorbed into the blood.

INTERNAL ADMINISTRATION OF NITRITE OF AMYL AS A STIMULANT IN THE TYPHOID STATE.

BY JOHN M. KEATING, M.D.

I REPORT the following not because I deem the matter contained therein conclusively proven by the case narrated, but simply to encourage those who have the opportunity to investigate still further in what may become an important field in therapeutics.

My case was carefully and intelligently watched by the then resident physician, Dr. Philips, and the reports submitted are mainly taken from his notes at the time.

I. O., a colored man, aged 32 years, was admitted to the medical wards, Philadelphia Hospital, on Monday, March 4, 1878, at 11 A.M. He stated that he had been taken with a violent chill on Friday night, followed by fever and copious perspiration. On Saturday and Sunday he was chilly and unwell, had a dry, hard cough, a severe headache, and spat blood.

After his admission his condition was as follows. Respiration 66, very shallow; a severe, constant pain, increased in severity by the slightest effort, felt at base of left lung; this pain radiated to apex of same side. Hasty examination revealed marked dulness on side and back of left lung. At this point breathing was tubular, and at the margins, with deep inspiration, crepitant râles. At right apex there was dulness, prolonged expiration, which at the time was noted as a chronic trouble.

The base of the right lung was normal, though somewhat exaggerated, as probably most of the aeration was done by this lung. The temperature was 104°, and the pulse 110. He was ordered wet cups over left lung posteriorly, and dry cupping *ad libitum* over whole thorax. This was followed by a poultice. A moderate dose of opium with ten grains of quinia was given at once.

The case was recorded as one of acute pleuro-pneumonia in first stage, affecting the left lung in an anæmic adult negro, with consolidation of the apex of right lung that had not yet begun to break down. At three o'clock P.M., owing to the weak pulse and general evidences of great prostration, stimulants were indicated. The pains had somewhat abated, the sputa were free and were well tinged with blood. The temperature had gone up to 106°.

No form of stimulants, for some reason, could be obtained. It occurred to me to use *nitrite of amyl*, which I had heard had been used to prolong the "*stadium alcoholicum*" by some devotees.

Three drops of the nitrite were ordered in emulsion every three hours, and all other medication stopped.

At nine next morning the patient was reported as decidedly more comfortable. The temperature was still high, 105⅖°; the pulse had fallen to 96, was good, full, and regular; respirations were 50, easy, and deeper; the pain was not severe. He had taken four doses of the nitrite mixture.

I give below his temperature record for four days and nights, after which he continued to improve until he got entirely well of the pleuro-pneumonia and nothing remained but the consolidated right apex.

Up to 10 A.M. on the 6th, the third day after his admission, he had taken twelve doses of the nitrite of amyl, no alcoholic stimulants, and no other medicine of any kind.

March 5.—10 A.M., pulse 96, resp. 32, temp. 105⅖°; 2 P.M., temp. 104⅘°; 6 P.M., temp. 105½°; 6 P.M., temp. 104°; midnight, pulse 98, resp. 30, temp. 103⅖°.

March 6.—10 A.M., temp. 103°; 2 P.M., temp. 102⅖°; 9 P.M., pulse 90, resp. 42, temp. 102°; midnight, temp. 102⅕°.

On the 7th, the fourth day after admission, the temperature varied between 102° and 103°; the pulse went down to 88.

On the 8th the temperature did not go higher than 100⅗°, the pulse registered 84, and the respirations were 36.

For several days the nitrite of amyl was given three times daily, and occasional doses were administered until auscultation and percussion showed that air was freely entering the lung. In this case there was from the commencement a tendency towards the typhoid state, and the very rapid improvement which ensued from the treatment was attributed to the nitrite of amyl as the only drug given.

NOTES OF HOSPITAL PRACTICE.

LOUISVILLE HOSPITAL COLLEGE OF MEDICINE.

CLINICAL SERVICE OF DUDLEY S. REYNOLDS, M.D., PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE HOSPITAL COLLEGE OF MEDICINE.

Reported by A. H. KELCH, M.D., Stenographer.

ON THE EYE.

(Continued from page 143.)

CASE V.—Mrs. K., aged 59 years, comes here with a tumor in the upper margin of the left brow. It is hard and at times painful. The skin covering it is glossy and tense. It is a steatoma or sarcoma, and I shall remove it. Making an elliptical section of the tense skin, we see a pulpy, semi-translucent mass of cellular substance, not unlike brain-substance. I think it is medullary cancer, of the encephaloid variety. It is developed by a peculiar retrograde metamorphosis of the cells composing the tissue in which the morbid growth is developed. What condition determines the retrograde metamorphosis of cells is something that has not yet been discovered. A cancer is primarily of local origin, affecting the system secondarily through the agency of the lymphatic glands, which become obstructed, and through the colliquative discharges from rapid suppuration. The neighboring glands here are already infiltrated with cancer-cells, no doubt. That being the case, we cannot, of course, hope to eradicate this affection from the system by the operation I have just performed. I believe in Henry Arnott's theory of the local origin of cancer. The popular opinion is that cancer is a kind of parasitic growth, and it is inferred, from its common name, that it is a kind of crab. It has long since been determined that the microscope does not reveal any special kind of cell as characterizing a growth of what is termed cancer. There is no specific cancer-cell, but we recognize a tumor as cancerous in which embryonic cells predominate. Then the nature of a cancer is this, that the cells which form the normal tissue, instead of going on in the process of development, assume the form of the cell in embryonic life, and these go on accumulating by proliferation or aggregation in the part until they become the predominating cell. If these cells are round, we call the tumor in which they are

found round-celled cancer; if they are very large, we call it a giant-celled cancer; and if star-shaped, stellate, which is the form, generally speaking, peculiar to melanotic cancer, black cancer, more frequently observed in the liver and lung. There are some forms characterized by filiform cells, and you are to understand that in any tissue of the body where the embryonic cell is formed, it means cancer, and the shape of the cell will depend much upon the tissue in which it is found.

Its essential pathology consists in a retrograde process of the cell-change, which finally undergoes fatty degeneration, and in other instances the cells simply break down into granular matter, and the fluid portion infiltrates the contiguous structure. From what I have said about the local origin of cancer you can understand how it happens that recovery sometimes occurs from enucleation. In Gross's "Surgery" is detailed a case which recovered from encephaloid after the twenty-third operation; and other instances of recovery are not wanting.

Case VI.—Mr. George T. M., of White Mills, Hardin county, Kentucky. This man is thoroughly saturated with malaria; he has a poor appetite, bowels constipated, headache, and general malaise. In the left eye he has suppurative keratitis accompanied by powerful contraction of the orbicularis palpebrarum. The corneal epithelium is shaved off the upper half, and in the inferior and outer quadrant of the cornea is a mass of suppurative matter.

He has been treated by Dr. Ashlock, who gave him atropia and morphia as a local application, and iron, quinine, and iodide of potassium constitutionally. He is now evidently better, as there are unmistakable signs of resolution of the inflamed cornea, and the breach of continuity is beginning to be repaired, as is shown by the smooth-bevelled edges of the ulcer.

This is a typical case of suppurative keratitis, nearly always due to malarial poisoning,—at least, as it is observed in this part of the country; and these are the cases which afford the most striking illustration of the therapeutic value of calomel. Whilst quinine is necessary, calomel is likewise essential. I have never yet seen a man suffer from suppurative inflammation of the cornea without a disposition to constipation, general malaise, loss of appetite, scanty urine, and other evidences of the constitutional effects of malaria.

After releasing the eye from pressure and friction of the lid by a canthoplasty, I expect to see him recover promptly under the use of calomel and quinine constitutionally, and a continuation of the morphia and atropia locally. Having forced the cornea from the injurious friction of the upper lid, whose lining membrane is somewhat roughened by long-continued inflammation of the cornea, and by its passage over the roughened ocular conjunctiva, which is never absent in cases of suppuration or other forms of keratitis, and particularly in those cases where the iris is also involved, recovery will be rapidly completed.

This disease, no doubt, began in the iris, and with the development of the serous form of iritis there is a proliferation of connective-tissue cells in the posterior elastic layer of the cornea, or upon its surface, thus propagating the disease to the proper substance of the cornea, causing what is commonly called suppurative keratitis, which begins in fact by the effusion of plastic material in the proper substance of the cornea, subsequently breaking down all the affected tissue, leading generally to perforation.

To the treatment employed by Dr. Ashlock, Mr. M. is indebted for his good fortune in escaping that calamity. Under the use now of calomel and quinine for four or five days, until the more violent symptoms of inflammation have subsided, followed by the iodide of potassium or syrup of the iodide of iron, I confidently expect this man to regain his strength and health and have a restoration of the sight of his eye. The amount of the tissue destroyed, the actual destruction of the proper substance of the cornea, will mark the extent of the remaining opacity, which in this case is likely to be so small and so far removed from the vertex of the cornea as to place it out of the line of vision and therefore occasion but little obstruction to sight. The canthoplastic operation which I have just performed gives him immediate relief from the sense of friction, which was a source of great suffering to him before. The stitches introduced are to be removed in twenty-four hours, and in the mean time he is to keep his eyes

constantly bathed in cold water. He goes to St. Joseph's Infirmary, with instructions to remain in-doors until further orders.

Case VII.—Mrs. D., of Lebanon, is now 50 years of age, which is above that at which the accommodative power presents any difficulty to the process of testing the refraction. The decline in the accommodative power occurs simultaneously with that of the body in general, and constitutes the earliest sign of senility. She comes to get glasses. But, upon examination with the ophthalmoscope, I find an unsuspected and very interesting condition. She has retinitis pigmentosa, an inflammation of the retina which is always characteristic of constitutional specific disease. She has had a perforating ulcer in the left cornea, and retinitis has existed a long time in the right eye. The disease is probably syphilitic. Galezowski says that the bichloride of mercury given to the production of its constitutional effects constitutes the only successful form of treatment in retinitis pigmentosa; he does not think much of the biniodide of mercury, or of the protiodide, or in fact of any other than the corrosive chloride. He uses the corrosive sublimate in the dose of one-twenty-fourth grain, which, if it act too severely upon the bowels, is controlled by paregoric.

I mention him as authority because I like his papers on retinitis pigmentosa. I believe if there is anything like a specific treatment in this disease, if there is any improvement to be obtained, if there is any power to arrest the disease, that power is found in the bichloride of mercury. Small doses systematically and regularly administered until the gums become tender, followed by the ordinary doses of iodide of potassium, four or five grains, gradually increased for three or four days, until iodism is produced, will yield the best results. These will, of course, be assisted by out-door exercise, salt-water baths, and everything that will tend to keep up a strong and vigorous action of the whole system, and facilitate excretion by the skin, bowels, and kidneys. This patient is now fifty years old; there is no telling how long she has had this trouble. It may have been acquired, although Mr. Hutchinson and Galezowski have expressed the opinion that this is one of the manifestations of inherited disease. They may be correct.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

CLINICAL SERVICE OF PROF. ASHHURST.

Reported by JOHN M. TAYLOR, M.D.

CASE OF CYSTITIS WITH ENLARGED PROSTATE AND RECTO-VESICAL FISTULA, TREATED BY SIR HENRY THOMPSON'S METHOD OF INTRODUCING A TUBE INTO THE BLADDER THROUGH AN OPENING ABOVE THE PUBIS.

THIS patient, a man somewhat advanced in years, had been in the hospital several months, suffering from inflammation of the bladder and very great enlargement of the prostate. There was no retention of urine, with vesical distention and secondary overflow, such as is so often met with in cases of prostatic hypertrophy; but, on the contrary, the bladder was very much contracted, the patient micturating on an average once in every half-hour or hour with intense pain, and the catheter not bringing away more than a fluidounce of very offensive and dark-colored urine. The patient himself declared that there was an opening between the bowel and the bladder, and that he had on one occasion passed several grape-seeds *per urethram;* but, as there was no escape of urine from the rectum, and no appearance of fæcal matter in his water, this was supposed to be a mistake, though, as it was afterwards found, such an opening actually existed.

Apart from the fact that there was no urinary retention to require the use of the catheter, the employment of this instrument caused increased pain, and hence was not persisted in, and as internal remedies (including ergot and the chlorate of potassium) had utterly failed to give relief, the case was thought to be one in which it would be justifiable to adopt Sir Henry Thompson's suggestion of establishing a direct communication with the bladder above the pubis, an operation which finds its analogies in colotomy for rectal stricture, and in tracheotomy for occlusion of the larynx. This operation has been practised in five cases by Sir Henry himself, with decided, though only temporary, benefit in each instance; and a similar procedure has been employed by Dittel, of Vienna, and by Prof. Keyes, of New York, but, so far as is known, has not been heretofore attempted in Philadelphia.

The patient, having eagerly assented to the suggestion of any operation which might offer even a hope of relief, was etherized and brought before the clinical class of the University on Saturday, November

20, 1880. About three fluidounces of tepid water having been carefully injected into the bladder, the long styleted tube, made by Mr. Gemrig exactly according to Sir Henry Thompson's description, was introduced through the urethra, and made to push up the anterior wall of the bladder, immediately above the pubis. The instrument being then confided to an assistant, Dr. Ashhurst made a longitudinal incision about half an inch in length, exactly in the median line of the abdomen, cutting down cautiously upon the bulbous end of the stylet, which, followed by the tube, was thus made to project through the wound. The stylet being next withdrawn, a tube shaped like a tracheal canula, and two and a quarter inches long, just large enough to fit inside of the large urethral tube, was introduced its whole length into the projecting end of the latter, and, as this was slowly withdrawn, was thus carried into the bladder, its safe lodgment in the viscus being announced by a free gush of urine mingled with the water which had been previously injected. The tube was then secured in place by means of tapes passing around the hips and thighs, and the patient returned to his bed.

The only point in which the operation differed from Sir Henry Thompson's was in the use of a metallic instead of a flexible vesical tube. This modification was decided upon, Dr. Ashhurst said, because he could not obtain any flexible tube which would be sufficiently permanent to be of value, and because the greater facility in cleansing and reintroducing the metallic tube would, he thought, compensate for any risk of its producing undue irritation. To guard against the latter contingency, the tube was made with a movable plate, after the manner of a tracheal canula.

When the patient was visited in the ward, about an hour after the operation, it was found that fæcal matter was mixed with the urine which flowed through the vesical tube, thus showing that the patient's suspicion that there was an abnormal communication between the bladder and gut had been well founded. The operation has been followed by no constitutional disturbance whatever, and there has been measurable relief from pain, so that it may be considered to have accomplished what was expected from it. It is hoped that when the patient shall have learned to manage the tube for himself, he will be placed in a condition of comparative comfort. The enormous size of the prostate must prevent any attempt to relieve the recto-vesical fistula by operative measures, and, indeed, all the circumstances of the case are such as to forbid any expectation of effecting a radical cure.

TRANSLATIONS.

Symptomatology of Tumors of the Mediastinum.—In an elaborate article on this subject, illustrated by several clinical histories of rare cases, Dr. A. Schreiber (*Deutsches Archiv für Klinische Medicin*, Bd. xxvii., 1880, p. 52) gives numerous points in symptomatology which are of considerable importance. Hertz, he reminds us, has said that the appearances presented by new formations of the mediastinum are entirely dependent upon their size, the rapidity with which they develop, their locality, and the pressure which they exert upon the important organs of the thoracic cavity, heart, lungs, trachea, and bronchi, the œsophagus, and particularly upon the larger vessels and certain portions of the nervous system. Small, soft tumors, adds Schreiber, hardly ever give rise to pathological symptoms; the latter do not appear until the tumors have reached a certain size. One of the earliest complaints, difficulty of respiration, at first observed only after unusual exertion, later constant, and sometimes going on to dyspnœa or even orthopnœa, and possibly terminating in suffocation, is found to be due to compression of the trachea and bronchi, or rather of the recurrent vagus. This may give rise to a feeling of compression at a particular point in the neck. At the same time pain in the sternum, usually dull, but sometimes sharp and burning, and which may radiate into the neck and arm, is felt. The disturbances of the general condition which may occur are various. Sleeplessness, usually dependent upon the difficulty of respiration, is one. Pleuritic effusion may prevent the patient from lying on the affected side or even lying in bed at all, as in the case of a patient of Fuller's, who was obliged to sleep kneeling, with his head on his hands, in a bed made especially for the purpose.

The temperature, which is sometimes increased, shows no typical range, and is

probably dependent on some intercurrent disorder; it is not characteristic of the tumors. Loss of appetite and nutrition is at times noticed, probably as a result of the general condition; it is worse if associated with difficulty of swallowing. Attacks of syncope, dizziness, muscæ volitantes, etc., are due to unusual circulatory disturbance, and are not met with in most cases. Dry, irritating cough, with mucous or muco-purulent expectoration, occasionally mixed with blood, is among the most annoying symptom of mediastinal tumor. It is due to compression of the recurrent nerve, which also may give rise to weakness of voice through relaxation of the vocal cords, and occasionally œdema of the glottis. Compression of the vagus sometimes causes difficulty in swallowing, hiccough, and vomiting. Occasionally these symptoms may be caused by direct compression of the œsophagus by the tumor. In a case reported by Todd this alone caused death.

With regard to external symptoms, the grayish-yellow complexion of the patient is characteristic. More important is the not infrequent occurrence of cyanosis. The pupils are sometimes asymmetrical or otherwise changed. Rossbach gives a case where pressure upon the middle part of the right supraclavicular region invariably caused sudden dilatation of the pupils. Coolness of the extremities is often noticed, and œdema sometimes occurs. Strumous swellings are sometimes observed.

The respiratory sound is most weakened over the seat of the tumors, as are also the heart-sounds. The pulse is usually small and frequent (100–136 in some cases). Enlargements of the glands are frequently observed.

The skin shows increased sweating, sudamina, etc. The mamma of the affected side may be enlarged, usually being pushed out by the tumor, but venous obstruction may also give rise to such enlargement. Disturbances of sensation, as formication, etc., neuralgia, and paralysis, all due to pressure of the tumor on nerves, are rarer symptoms.

Differential Diagnosis of Tumors of the Mediastinum.—Schreiber (*Deutsches Archiv f. Klin. Med.* Bd. xxvii. p. 66), in a paper on tumors of the mediastinum, a portion of which we have given above, says that these are to be distinguished from pericardial effusions, pleuritic exudations, aneurisms, partial infiltrations of the parenchyma of the lung, mediastinitis, and mediastinal abscesses. With reference to pericardial effusions, of course only chronic cases are to be considered. The usual fever accompanying these and also the area of dulness on percussion will serve to distinguish these as well as their clearly-defined limits. Articular rheumatism, Bright's disease, pyæmia, etc., are usually concomitant with pericardial effusion; the apex-beat of the heart is muffled, and a rubbing sound is heard. None of these phenomena occur in mediastinal tumors. The diagnosis is often extremely difficult, however. With reference to the differential diagnosis between mediastinal tumors and aortic aneurism, this refers only to cases where the aneurism is of considerable size and presses against the anterior wall of the thorax,—cases in which there is dulness under the sternum. Here the rarely perceptible resistance of the area of dulness when percussion is made, the visible or palpable pulsation, the usually systolic murmur, the retardation of the pulse in the peripheral arteries, serve to aid the diagnosis under ordinary circumstances. Now and then, however, unusual combinations of lesions may occur which cause great difficulties in diagnosis. Such are the effects of compression on the œsophagus, the larger veins, the recurrent nerve, etc. Also in cases where a firm tumor lies farther back and presses the aorta forward, giving rise to phenomena of pulsation. In one case cited by Schreiber it was impossible for two years, during which the patient was under observation, to find out whether or not an aortic aneurism was present. Pleuritic exudation can usually be distinguished without great difficulty; in case of doubt some fluid may be withdrawn by aspiration. Now and then the two conditions exist together, which adds greatly to the difficulties of diagnosis. Infiltration of the borders of the lungs is very rare, and may be distinguished from mediastinal tumor by careful percussion. Mediastinitis is usually accompanied by fever, etc., and the dulness on percussion is not often so decided.

Although, as has been shown, careful investigation will usually lead to a correct diagnosis of tumors of the mediastinum when uncomplicated, yet when these occur in connection with other troubles it is

almost impossible at times to arrive at a satisfactory conclusion.

PREVENTION OF MERCURIAL STOMATITIS.—Dr. Jules Simon recommends the following preparation to prevent the development of mercurial stomatitis in a course of antisyphilitic treatment:

℞ "Eau de Botot" (artificial), f℥vj;
Tinct. cochleariæ, f℥iiss;
Tinct. cinchonæ, f℥ii;
Tinct. catechu, f℥i;
Tinct. benzoin., f℥ss.—M.

A small quantity is mixed with water and used as a gargle morning and evening and after meals.

TREATMENT OF INFANTILE SYPHILIS.—Dr. Jules Simon, in a lecture published recently in *Le Progrès Médical*, recommends the following course to be pursued. Inunctions with *ung. hydrarg.* to be made every night and morning, alternately, in the armpits, the groins, and the popliteal spaces. Five drops of Van Swieten's liquor to be taken four times a day gradually, augmenting the dose until twenty drops are taken at a time. A wooden or porcelain spoon should be used. This treatment should be continued a long time,—months at least. The medication should not be suspended during the first period, but the dose may be increased or diminished, depending on the progress the patient is making. We must feel our way. When, for instance, the skin of the patient's face regains its transparency, the nose is open, the anal region is smooth, when sleep is natural and calm, the dose of medicine may be reduced drop by drop. At the least sign of return of the skin manifestations the dose of Van Swieten is to be increased. The cutaneous frictions should be managed in the same way, being reduced in number and extent, but never wholly suspended, during the first five months. At the end of four or five months the concomitant internal administration of iodide of potassium is begun. *Syrop Gibert* is the best form to give this: a quarter to a half dessertspoonful may be given daily, much diluted in water and divided into four or five doses. The dose is to be increased or diminished from time to time according to the effect produced upon the lesions. When the infant appears to be restored to perfect health, the medicine may be slowly reduced in quantity and finally stopped, a careful watch being kept against the recurrence of any symptoms. Dr. Simon does not favor the use of mercurial baths. He thinks that either they are too short and only act locally, or they are too prolonged and tend to enfeeble the child. Besides, there is constant danger of catching cold, to the action of which infants are extremely susceptible. As a lotion, particularly where there are lesions about the anus and buttocks, the sublimate solutions are valuable. Syphilitic infants should be kept in a warm atmosphere and should not be taken out in cold weather. It is hardly necessary to say that the mother alone should nurse her child. Failing this, cow's milk may be employed, although with much less success. By hard work, continues M. Simon, you may succeed in snatching the unfortunate infant from the jaws of death. Do not, however, rest in a false security when it appears cured; guard carefully against relapses. Tell the parents to submit the infant frequently to the inspection of the physician, and then, if the least spot or blemish appear, indicating a tendency to return of the trouble, begin treatment once more. Even quite large children must be watched thus, and must occasionally be placed upon a new course of mixed treatment.

REFLEX SYMPTOMS IN PATIENTS OPERATED UPON FOR EMPYEMA.—At a recent meeting of the Société de Biologie (*Le Progrès Méd.*, 1880, p. 846) Dr. Dumontpallier reported the case of two patients operated upon for empyema where certain accidents had taken place some weeks after the operation, when the cure seemed almost complete. In one case, that of a woman, Dr. Dumontpallier injected some tincture of iodine by the opening into the thorax. Scarcely had a few drops penetrated the thorax when the patient suddenly fell into a condition of syncope and remained several minutes without breathing, being brought to with difficulty afterwards. Up to that day the patient had supported the injections perfectly well. The second patient, a man of forty, had been operated upon eighty days previously. The adhesions had been so considerable as to leave only a small cavity containing only a little liquid. At the moment when a little carbolized water was being slowly injected into this cavity, the patient was suddenly seized with general contraction of the muscles on the opposite side of the body. This lasted some minutes, and was followed by incomplete paralysis.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, DECEMBER 18, 1880.

EDITORIAL.

THE UNIVERSITY OF PENNSYLVANIA.

AMONG our miscellany is a paragraph which was penned by one of the trustees of the University of Pennsylvania, and which may therefore be looked upon as a semi-official statement of changes about to be perfected in the organic methods of that ancient and venerable corporation. The old proverb about the foul qualities of a certain bird which does a certain act is, perhaps, a useful although a much abused one; and yet, if it had not been for the public showing of how soiled the family linen was, made some years ago in the pages of *Lippincott's Magazine* and of this journal, it is very possible that the medical department of the University would not now be what it is. The action of the Board of Trustees shows that they recognize the need of changes in the method of management of the University; but, as these changes have not yet been more than fairly entered upon, perhaps it may be well to call the attention of the University authorities, and of the interested public, to certain undeniable facts.

It seems to us very important that it should be generally recognized that the career of the University has been a most lamentable one, one disgraceful in the extreme, either to the community in which it is placed or to those who had charge of it, or else a failure, because of the bad methods upon which its life has been founded and nurtured. The institution is over one hundred years old; it was cradled during the infancy of the great city which envelops it,—a city whose fame is in all the earth. For decades it was the only higher institution of learning not only in this city of Philadelphia, but also in the State of Pennsylvania. Has it grown with the city? Has it dominated the life of the citizens? As the millions of property multiplied about our streets by the hundredfold, have its coffers been filled? What are the area, population, and wealth of Boston to those of Philadelphia? Omitting the medical department, the growth of which has not been due to the University, what is the University of Pennsylvania, in its influence, to Harvard? It may be said that Harvard has grown because Boston is more cultured. Nay, verily. Boston is more cultured because Harvard has permeated it with its influence. The strong liquor is not strong because the spirit has made the leaven, but because the leaven has made the spirit, though the leaven may increase in the process.

Whilst charities multiplied,—whilst millions were found for orphan asylums,—whilst refuges for the deaf, blind, halt, lame, institutions of every character, grew apace,—for nearly three-quarters of a century practically if not absolutely nothing was donated to enrich the University: so at least it is affirmed.

It is essential that we perceive the weakness, the impotence, in order that we should be able to search out the cause. During the last two decades there has been no lack of energy, of devotion, or of business talent in the Board of Trustees; of their own substance they have given bountifully; they have dared much; they have accomplished much; and whilst they have demonstrated the comparative feebleness of the hold which the institution has upon the community,—the legacy left them by a long line of feeble (to use no stronger word) predecessors,—and have accumulated much of debt, they have made the University a centre which Philadelphia can begin to be proud of; they have laid a foundation upon which to appeal to all friends of education, all patriotic Philadelphians.

We have, perhaps, occupied too much space in stating these facts, but our readers were scholars before they were doctors; and the present seems full of hope, because the recent action of the Board of Trustees is evidence that they perceive the difficulties of the situation, and have the self-abnegation to lay aside power.

The reasons of the lamentable failure of our University seem to us to have their roots, first, in the methods of its government; second, in the method of the appointment of the trustees. The theory of the government of the institution has practically been that each department was managed by its own faculty, superintended by a committee of the Board of Trustees, whose chairman was the more or less indifferent autocrat of the department. Of course, this resulted in the University being not a homogeneous educational community, but a collection of educational villages, between which there might be concord, indifference, or jealousy, the truth being that at the present time many, possibly the majority, of the University professors do not know one another by sight. The recent action of the Board of Trustees ends this. At last this nondescript collection—of which we have been at once so proud and so humble—is to have a real head; and we may hope soon to see all the faculties working together with that *esprit de corps* which comes of union and recognized brotherhood. This is well,—a step in advance so great that it leads us to hope that more will follow.

The second cause of the failure of the University—one not yet remedied, one which has to our thinking been the veritable *fons et origo mali*—is the method of the appointment of the trustees.

They are a self-elective body, responsible to no one, reporting to no one, filling their own vacancies by their own wills. Yet a university must grow, if it grow at all, by the efforts of its alumni; it is chiefly their sons and their friends who are to fill its halls; it is chiefly they who are to give renown to and extend the influence of the alma mater. Is it the faculties of Harvard or is it the roll of its famous alumni that gives most brilliance to its lustre?

If alumni are to keep alive their interest, to give their money, their influence, and their time to an institution, they must have some control and some representation in the governing board of the institution. The simplest, and therefore it would seem at first sight the best, plan, is to have a *portion* of the Board of Trustees elected by the alumni. In the long succession of years we believe that this would keep the *personnel* of the board uniformly higher than the present plan. Too much praise cannot be awarded to the present governing body, but the history of the University shows the danger, under the present methods, of the formation of cliques and lines of undue influence. It is not this, however, that we desire most to guard against. Our complaint is that at present the best Board of Trustees represent—whom?—themselves, that is all.

More spiritless, and we had almost said more useless, assemblies we have never attended than the annual meetings of the alumni societies; but if it were known that reports were to be read by representatives from the Board of Trustees, and that elections were to take place for such representatives, that general plans of policy, as well as details of execution, were to be discussed, that representatives were to be instructed when questions of sufficient magnitude arose, it would be like opening wells of water in the Sahara: the deadness of the desert would be swallowed up in the fertility, the teeming life, of the oasis.

The charter of the University may require the appointment of the trustees as at present; but the life of the institution is more than the charter. If necessary, let the latter be amended. At the same time, we do not assert that the adoption of the

exact change here approved of is essential; it may be even that, under the present complicated circumstances, it is not the best way of accomplishing its object,—namely, the giving of direct representation to the alumni in the government of the institution.

Alumni of the University, if you love your old alma mater and wish its prosperity, now is the time to meet, to discuss and to express in unmistakable terms what is needed.

It is no secret that Dr. William Pepper has been nominated for the position of trust just created by the Board of Trustees of the University. Without wasting words, we may state our belief that in the existing circumstances the best man that the board could have chosen has been selected. The duties of the position as now arranged are such that they can be fulfilled without the sacrifice of much time, and Dr. Pepper does not expect in any way to relax his efforts either as a member of the medical faculty of the University or as a practitioner of medicine.

POTENTIZATION.

PERHAPS the human intellect never conceived an idea sublimer in its absurdity than the homœopathic doctrine of potentization, which may be expressed briefly as the theory that teaches that the differentials of inert substances like chalk are prime forces in the universe. (Our readers will remember, no doubt, from their boyhood studies, that the differential of a vanishing number is that quantity which it is when vanishing, *i.e.*, when it is no longer anything, and yet is not possessed of the proprietary rights and privileges of nothing.)

Some years since, a medical student was complaining to us that his family tormented him by constant efforts to make him leave the University for the Hahnemann College. On asking how it was that under the circumstances he had not studied homœopathy, he replied that he had intended so to do, but one day their family doctor took a small vial out of his pocket and said, "Look at this, John: it is my most precious possession. Twenty-five years ago I put a fraction of a grain of chalk in it, and filled up with sugar of milk. Day after day ever since I have used out of this bottle, replacing the contents as they waste with pure sugar of milk, and now I have a most powerful energy for good confined there." The man was sincere, but his imbecile enthusiasm was too great a dose for the gulping power of the boy. He could not believe that the miracle of the widow's cruse of oil should receive in these modern times infinite repetition.

In the *Homœopathic United States Medical Investigator* for October 1 a contributor, with Hollandish stolidity, relates the following

"*REMARKABLE EXPERIENCES OF AN ACONITE BOTTLE.*

"Over thirty years since I got a little aconite leaf at a drug-store. The druggist cut off a little slip not one-half as much as your little finger. I asked him how much for it? He says you are welcome to that little. I put it in a vial holding about two ounces, and filled it with half alcohol and half water. This preparation I used on every occasion of sickness of horses and cattle owned by myself, and many of my neighbors, for about fifteen years. Every creature which took the medicine got well. From five to ten drops at a dose was all that was used, and then not more than three to five doses. Some animals had other medicines after it, but all got well. The vial would get dry by evaporation, or used out, and all that we done was to put in alcohol or water. I gave the vial to a son-in-law of mine, after using it myself fifteen years, having first cured for him a horse sick and down with the colic with it. He has at times had charge of twenty and thirty horses, and when anything was the matter the little aconite bottle came out as the first thing, and generally the only thing. He of late sold out his horses and gave the bottle to the men he sold to, and they use it just the same. No medicine has been added in thirty years, but often filled with alcohol and water. Not one horse died in sickness if he took out of the little bottle. I think the little bottle good for thirty years more if kept filled, and will do just as well as ever. This may appear strange, but it is true. More are killed with medicine than cured."

The theory of potentization and the structure built upon it seem, however, destined to death; and the unkindest

blow has come from a homœopathic medical society. Well may some of our struggling brethren exclaim, *Et tu, Brute!*

The Milwaukee Academy of Medicine (homœopathic) distributed to believers of high potentization carefully-prepared vials of medicine. Each individual received ten vials, nine containing only pellets of milk-sugar, and one having in it globules of a high potency of aconite. The endeavor was to distinguish the medicated sugar by its effects on the human system. Twenty-five believers, residents of twelve different States, sent for and received the vials. Concerning these, the final report, as adopted by the Academy, reads thus:

"Number of tests applied for and sent out, 25.
"Number of tests on which reports have been received, 9.
"Number of tests in which the medicated vial was found, 0."

From which it appears that sixteen of those who undertook the task did not venture on any report, whilst not one of the nine who did report indicated the right vial.

The test and its results have called forth no rebutting evidence of value, only considerable abuse of Dr. Potter, president of the Academy, which is evidence of its truthfulness and value.

CORRESPONDENCE.

LONDON LETTER.

THE medical world of London is very quiet at present, and the schools are settling down into their stride for the serious work of the winter session. The improvement in the entry at the London Hospital is marked. Situated at the East End of London, even its able staff failed to attract to it students in proportion to its teaching power. But railway facilities at last brought it within ready reach of the rest of the world; and this, combined with a little extra energy on the part of the governing powers, has begun to tell upon the entry. At Guy's the entry was much larger than was anticipated by the profession in the face of the present imbroglio. Clouds are suspected to be gathering for the London Hospital, as the new matron there just appointed is the lady who recently worsted Dr. Humphry at the Pendlebury Hospital, near Manchester. The profession is beginning to realize that there is a "screw loose somewhere" in its social position, when the appointment of a matron is regarded as the herald of approaching trouble and probable disaster. However, as people make their bed, so must they lie; and the medical profession is finding out that it is no exception to this law. The profession has not always and invariably with true loyalty to itself put the best man into the vacant post,—a principle which ought to be as conservative as chastity in a woman; and now clouds of gathering storm are to be seen in the distance to supplement the rows which have already taken place. But, be that as it may, the real merits of the profession are too solid for its errors to dim its reputation permanently.

The subject of typhoid fever is being discussed at present from various stand-points. We are all under the impression that typhoid fever is exclusively, or nearly so, communicated from one person to another by means of the stools of the affected person. That fact has been vividly, indeed painfully, demonstrated by various outbreaks, as, for instance, a recent one at Caterham, where an extensive outbreak was clearly traced to the stools of one workman affected with ambulatory typhoid, portions of which found their way into the water-supply of an extensive area, the result being a wide-spread outbreak of typhoid. All who have had experience of country practice know too well how a single case of typhoid, acquired at a distance, comes into a hamlet and is followed by the appearance of several cases in the neighborhood. Here the conclusion is inevitable that the sick person brought the fever-poison, and that from lack of knowledge, perhaps, rather than culpable negligence, the stools, or part of them, are allowed to reach the water-supply and contaminate it. Typhoid fever develops in an endemic form. Now, granting all this as indisputably proved, and as forming the basis of our knowledge of enteric fever, and realizing how such knowledge can be made practically useful in the prevention of its spread, still there are some other matters which must not be lost sight of. Foremost among these is this. If this view of the propagation of enteric fever is allowed to dominate the mind too completely, then there is a corresponding danger of our being forgetful, or practically so, of the other ways by which typhoid fever may be originated. Especially is this danger rendered probable by the prominence recently given to the accepted doctrine as to the etiology of enteric fever, by the attacks on an extensive scale which have occurred in connection with the milk-supply in various localities; and not only in typhoid fever, but in other specific fevers, notably scarlatina. But the other aspects of the production of typhoid fever must not be entirely overlooked.

In a recent letter I pointed out how outbreaks in Germany had been traced to eating meat which was not fit for human consumption, to put it broadly. Now some further evidence is furnished by a thoughtful article contributed by the pen of Dr. R. Bruce Low, the medical officer of health for a rural district in Yorkshire, as to the occasional origin of typhoid. He resides among a primitive people little addicted to migration, and firmly rooted, comparatively isolated; where there are no sewers and no sewer-gas, no water-mains with interrupted or contaminated supplies, but free supplies of pure water from springs issuing from limestone rock. There are there no surface-wells, tanks, or cisterns, —at least in the houses which furnished the fever cases. There was therefore no case originating in the drinking of water contaminated by specific discharges. The district is such as is familiar to the readers of Emily Brontë's "Wuthering Heights," and is far removed from any practical risk of typhoid infection, unless some case of the disease comes accidentally into it,—a matter which would soon be notorious.

One case given is that of well-marked enteric fever developed synchronously in a farmer's daughter and a shepherd residing in a cottage of his own, who alike ate some bacon which was "black and had a queer smell." It is surmised that the bacon was part of a pig which had been the subject of typhoid fever when slaughtered on your side of the Atlantic. This is a matter of considerable interest for the shippers of bacon cured in the Northwest States. In another case the cause of infection is carefully traced to a hide with putrid flesh attached to it, in a farmer who "never got over that smell." More generally interesting is the account he gives of a group of cases where no specific contagion could be traced, but where other factors were in action. In this district the cloacal arrangements are very primitive, and the chief method among the men is voiding their motions in the open air behind a fence, while the domestic arrangement is a privy with a large pit, which usually is rarely, if ever, emptied, and is full of fæces to the level of the seat. Here are motions years and years old; whether breeding infection in the course of time or not is a moot point not yet decided. In corroboration of the view that typhoid-fever germs may be in time developed from successive crops of bacteria, growing in infective power in each generation, he refers to the experiments of Burdon-Sanderson, "that it is possible to proceed from an inflammation of purely non-infective origin to the artificial induction of a process of the most intense virulence." He goes on to infer from this, "The gradual evolution of a contagion is, therefore, a demonstrated fact in science;" and from this we might argue that diarrhœal discharges received into a foul garden-privy in the first instance cause further and severer attacks of diarrhœa, the contagion after each attack becoming increasingly virulent, till the summit is reached, and typhoid fever, a specific contagious disease, is produced. In corroboration of this view he gives an example of a double cottage, which was occupied by ten persons (two families). The privies, some twenty yards to the rear, had, in consequence of a dispute, not been emptied for more than twelve months. First violent sickness and diarrhœa, with some bloody motions, showed themselves. There was some fever for several days, followed by rapid recovery. The attack was nearly fatal in three cases out of the seven attacked. Some visitors who remained in the rooms when the sick persons' bowels moved were seized with similar symptoms. So soon as the privies were cleaned out by the sanitary authorities the outbreak ceased. Three persons, males, who never resorted to the privies, escaped completely. He speculates as to the growth of typhoid from beginnings like these by relating a case which was seen by a second medical man and pronounced unmistakable typhoid, where there had been a case ending fatally, and certified as diarrhœa, in the house eleven months before. This case of typhoid ended fatally, and was followed by another case of true typhoid. Here the synthesis of typhoid seems fairly made out.

Some little time ago, when visiting in Somersetshire, I went with my host, a medical man, to see some cases,—one of undoubted typhoid, the other of diarrhœa with pyrexia and prostration,—such as those spoken of by Dr. Low, where the surroundings were very filthy, and fluid filth from a pig-sty found its way into the well of drinking-water till in the sunlight the water was opalescent. Though Dr. Low may not be said to have demonstrated his point beyond the possibility of cavil, it must be admitted that he has made out a case *a priori* so strong that he can fairly demand that country practitioners should investigate their cases of typhoid fever with the view of seeing how few a number are not originated by excreta from some already existing case of typhoid, but are, in some instances at least, bred up from filth and culpable dirtiness of habits. My experience as a country practitioner in the past certainly places me on Dr. Low's side as to the origin of some cases of typhoid fever.

That cases of typhoid coming in from a distance must be rare in that district, and the history palpable enough if occurring, is shown by the following details: "We have the same succession of heather, hills, moors, and bogs, wooded glens and mountain torrents, as in the scenes of 'Wuthering Heights.' Our people believe in ghosts. My predecessor in this practice has been seen (as it is said) more than once since his death. They believe in witchcraft and charms. Calves die from

spells cast by old women. Children take fits from 'evil eyes' being thrown at them, etc. As an example of our seclusion, I may relate an instance. My predecessor was attending a family (on a lonely moor) with diphtheria. The day after he saw them a heavy snow-storm came on, and, on making the attempt to reach the house, he failed, owing to the deep snow-drifts. He managed six miles, but the remaining three baffled him. A whole village set to work, and in five or six days cut a narrow path for him and his horse; but on his arrival he found four or five corpses in the house. Another example: Last winter, in a snow-storm, my colleague was sent for to a lonely house twelve miles off. He sent his assistant, who came back with the news that an operation for strangulated hernia was required. Next day my colleague and his assistant rode the twelve miles through the snow, and reached the house in the afternoon. As it was growing dark, they asked for candles, to afford sufficient light for the operation; but a messenger had to walk a distance of six miles over the snowy moor to the nearest village before he could get light sufficient for the operation. The delay, I regret to say, was against the success of the case, and the patient died." This will furnish the reader with an idea of what "country practice" is in some parts of Old England, and also tells how the neglect of all, or almost all, sanitary arrangements, from ignorance quite as much as indifference, may lead to diphtheria and typhoid fever,—indeed, to those maladies which are notoriously associated, causally, with filthy surroundings.

While on the subject of country practitioners it may be well to consider briefly what Dr. Angus Macdonald, of Edinburgh, has recently said about puerperal fever. Most of us can remember the time when the very thought of puerperal fever filled the medical man's mind with horror and dread. He knew of instances where a doctor had carried with him, in his function as an obstetrician, death to parturient patient after parturient patient, until the grim fact that he was the cause of death was forced upon his consciousness. Then he left his practice for some time, at a ruinous expense, partly from actual expenditure, partly from making nothing during the time, to return to realize the truth that a number of his best patients were dead, and that dismay and distrust reigned in the minds of those who remained. I, at least, can remember well what my father used to think on this subject. A contemporary of his had been the death of some dozen women consecutively, and had to leave his shattered practice for months before he regarded it safe to return. And it would rather surprise us now to hear how slowly the conviction dawned on these men of the past that the doctor was really the infecting agent; also, how dull must have been the apprehension of the moral culpability of remaining at work as obstetricians when death succeeded death. One of the grandest outcomes of antiseptics is the practical abolition of puerperal fever in an endemic form. Dr. Macdonald speaks of these antiquated plans of dealing with the spread of puerperal fever, and points out that now they are superseded. He points to the fact that it is in all cases "a true septic intoxication, a fever of resorption, and differs essentially in no wise from surgical fever." Abrasions and lesions of continuity of the lining mucous membrane of the fæcal tract favor absorption. Micrococci are the infecting agents, it would appear. A solution of one per cent. of carbolic acid is sufficient to destroy these minute organisms. The doctor must be careful to see that his clothes may not carry infection from one patient to another; no ablution of the hands, however perfect, can prevent that source of mischief from being operative. The bare arm must alone be used in connection with a post-parturient patient. As an evidence of the immunity attainable by proper precautions, he said that in the spring of 1879 he met with a case of puerperal fever in a patient of good social position, where for ten days he personally, twice daily, dressed a vulval ulcer and gave the vaginal douches. During this time he performed craniotomy, put on the forceps high up, practised turning, and extracted an aborted fœtus, without the slightest bad consequences of any kind. Had the remotest bad symptom showed itself he would have desisted from his obstetric labors at once, and without delay. As to his procedures, when called upon to examine or lift a patient suffering from puerperal septicæmia he always takes off his coat and rolls up his shirt-sleeves; he then washes his hands in turpentine or rubs them with carbolic oil. After his work is accomplished, then he washes his hands in turpentine and soap and water, using a nail-brush freely. Then he washes his hands in a five-per-cent. solution of carbolic acid, and finally puts them under a tap of running water. "Considerable importance," he says, "appears to me to be attached to the latter proceeding, as the running stream makes it certain that everything is carried away as well as washed off the hands. If a basin be employed the hands are brought from time to time into contact with any septic matter that might remain undestroyed in the basin." He is careful, however, while advocating the perfect protection afforded by resort to antiseptic precautions, to insist, "Nothing could be further from my intention in this contribution than to inculcate carelessness or do anything which could bring danger to patients or disgrace to obstetricians. But, on the other hand, I am anxious that everything should be done for unfortunate patients suffering from puerperal septicæmia which is consistent with fairness to the unaffected and

to the obstetrician in charge." He does not believe that the abstinence from practice advocated by certain obstetrical authorities is necessary or effective; indeed, he says it is not acted upon by these very preachers of the doctrine,—a rather strong statement.

He goes on to say, "For aimless and haphazard suspension from professional duty I would substitute the most thorough cleanliness and disinfection, believing that in the latter means the real safety of the patient lies. I have published my experience in this matter in the hope that it may encourage others to trust to and practise disinfectant appliances in similar emergencies." This principle of thorough, rapid, and complete disinfection ought also to be practised by nurses and midwives. If practised, he thinks it would not be so often necessary to change the nurses attending upon post-parturient patients. Midwives ought to be educated to use these disinfectant measures, as "time is only a very uncertain element in disinfection." He concludes with a strong expression of opinion that if these disinfectant measures were universally adopted the occurrence of puerperal septicæmia, in both private and maternity practice, would be largely diminished.

J. Milner Fothergill.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Thursday Evening, October 28, 1880.

The President, Dr. S. W. Gross, in the chair.

Large spindle-celled sarcoma of the sheath of the penis. Presented by Dr. W. G. Porter.

JOHN H. HENTON, black, widower for the second time, New York, æt. 44, temperate, was admitted to the Presbyterian Hospital on the 25th of August, 1880, and gave the following history. His health had always been good. He had never had any venereal disease, and he was the father of three healthy children. In March last, while employed as a porter in a large retail clothing-house, he was engaged in moving a very heavy package from a truck to the cellar, and while sustaining an unusually heavy weight, he felt something give way in his groin. He immediately dropped his end of the package, vomited, lay down, and felt so sick that he had to stop work. He went home and remained in bed for several days. He then returned to work, but in a few weeks noticed a tumor in the right inguinal region, which rapidly increased in size. Supposing that he was ruptured, he applied to an instrument-maker for a truss, who gave him a suspensory bandage. The tumor from this time enlarged very rapidly, and he was soon compelled to stop work, and applied to me for relief. On examination, a large tumor was found filling up the right groin, surrounding the penis, and extending deeply into the perineum. Neither testicle was implicated by the growth. The tumor was heavy and exceedingly hard. There were no evidences of fluctuation about it, and throughout the tumor felt as hard as a fibroid. There was no difficulty in passing water, and a bougie or catheter readily entered the bladder, and the course of the urethra could be easily demonstrated on it. As the man was incapacitated for work and the tumor was increasing in size, its removal was advised, and on the 27th of September, with the advice and assistance of the surgical staff of the hospital and of Prof. S. D. Gross and Dr. S. W. Gross, the tumor was removed. An oblique incision was made over the long axis of the growth, and after a rather tedious dissection by knife and finger the attachment was found to be to the right side of the sheath of the corpus cavernosum of the penis; only at one point, and that a small one, was the cavernous body itself involved. The hemorrhage was slight and was controlled by the ligation of several bleeding points. There was some capillary oozing, which was controlled by the application of hot water. The wound was carbolized, a drainage-tube inserted, the lips of the wound approximated by stitches, a compress and bandage applied, and the patient removed to bed. He soon came out from the ether, showed no evidence of shock, and seemed to be in good condition. In the early morning of the next day his belly became tympanitic, and he complained of the wound being tender and sore. The compress and bandage were removed, as there had been no oozing, and the wound was lightly dressed. He passed his urine without the assistance of the catheter. A turpentine enema brought away large quantities of gas. The following day the penis was swollen and the prepuce very œdematous; the belly tympanitic again. Enemas and the passage of a rectal tube failed to give relief. The patient suffered considerable pain; the tongue was dry; the edges of the wound dry, glazed, and erysipelatous; no discharge from the wound or drainage-tube; the penis became gangrenous; the belly remained tympanitic, and the patient died, exhausted, on the 1st of October, four days after the operation. Autopsy showed no evidences of peritonitis or cellulitis, though there was some very fetid gas in the peritoneum, but nothing but the local lesions already detailed to account for death.

Dr. Seiler said that he had made a number of sections from the tumor which had been sent him by Dr. Porter, and on examination had found them to consist of spindle- and round-cells of the large variety, the

former predominating, so that the growth should, in his opinion, be described as a large spindle-cell sarcoma.

Dr. S. W. GROSS said that through the kindness of Dr. Porter he had seen the tumor before its removal, and had then regarded it as a sarcoma. The operation plainly showed that it arose from the sheath of the right corpus cavernosum, which is continuous with the superficial perineal fascia, as was first demonstrated by Dr. Buck, of New York, and that it had invaded the tunica albuginea of the corresponding body to the extent of about two-thirds of an inch. He had looked up the literature of the subject, and the only reference he could find to a similar growth was a case recorded by Kochler in the *Charité Annalen*, 1878, and quoted in the *Index Medicus* for July, 1880. In a late posthumous work of Demarquay, published by two of his pupils, and entitled "Maladies Chirurgicales du Pénis," no mention is made of any such growths. From this he would infer that sarcoma was a very rare affection in this region, and that in all probability this case of Dr. Porter's was the only one that had ever been reported in this country.

Hypertrophy of the prepuce. Presented by Dr. J. E. GARRETSON.

Patient a native of the island of Barbadoes; age, 60 years. Associated with the enlargement and induration of the prepuce there was an apparent relaxation of the tissues of the scrotum, that appendage being some ten inches in length and of very little less width. The hypertrophy of part shown commenced several years back. When in place over the glans the full circumference of the structure seemed involved; when retracted the thickening was seen to be confined to one side. Removal was not attended by any hemorrhage. The case occupied the ordinary time of an operation for circumcision.

Tumor of mammary region. Presented by Dr. J. E. GARRETSON.

The tumor shown was removed from the superficial fascia overlying the right mammary gland of a lady aged 40 years. It is hard, lobulated, contracted. The concentration of the growth afforded indication for its removal. The time of development has been about two years. In the absence of anything self-explanatory the tumor is to be classified with the neoplasms.

Dr. S. W. Gross in examining the specimen thought that he could detect a distinct capsule, which would, of course, exclude the idea of carcinoma. As it had been kept some time, however, he might be in error, and would suggest the reference of the specimen to the Committee on Morbid Growths.

Dr. Garretson asked the President if he then considered it to be non-carcinomatous.

Dr. Gross replied that if this appearance of a capsule was not produced by the condensing effects of the preservative agent, and if he understood Dr. Garretson rightly as to its not involving the structure of the mammary gland, he should most decidedly consider it to be non-carcinomatous.

Report of the Committee on Morbid Growths.—"The tumor removed from the mammary region by Dr. Garretson, and referred to your Committee on Morbid Growths, is found upon microscopic examination to consist mostly of dense fibrous tissue, in which are seen the remains of glandular acini and ducts in a state of atrophy. The growth is an interacinous fibroma."

Nerve-tumor. Presented by Dr. J. E. GARRETSON.

The egg-like tumor upon the plate was removed from the very centre of the posterior tibial nerve of a gentleman aged 55. The growth is of several years' standing; it is allied to a similar tumor in relation with the outer cord of the lower cervical plexus. A tumor, supposed to be of like character, was dissected from the dorsal surface of the right index-finger. The growth shown had disparted the fibres of the nerve wherever it lay, and was the cause of much pain in parts supplied by the sacral plexus of nerves. The patient, himself a professional gentleman, had been treated a long time for rheumatism. The discovery of the tumor in the leg altered the treatment to that for neuroma. The growth removed from the finger is believed to have been an adenoma. The tumor upon the plate is reasonably to be designated a neuroma. It is presented to the Society for microscopical observation.

Dr. Seiler had examined the first growth removed by Dr. Garretson, and had found it to consist chiefly of blood-vessels whose endothelium was in a state of proliferation. The intervascular connective tissue was increased in amount. From such appearances he would class it as an angeioma. From a cursory examination of the section from the second tumor, now under the microscope, he would be inclined to consider it a spindle-celled sarcoma, but, to afford opportunity for a more thorough examination, he would ask for its reference to the Committee on Morbid Growths.

Report of the Committee on Morbid Growths.—"A thin section made from the tumor situated upon the tibial nerve removed by Dr. Garretson shows, after staining with carmine, numerous nuclei, which are separated by a very indistinct and granular or slightly fibrillated intercellular substance. In many places the arrangement of the nuclei and cells is that which is observed when a section of very young tendon is examined,—longitudinal rows of cells placed at regular intervals and surrounding a bundle of fibrillæ; at other points transverse sections of the fi-

brillæ have been made, when the stellate lymph-spaces are seen anastomosing with one another. We were unable to find any structure which would indicate the presence of nerve-tissue. The growth may be said to consist of embryonal fibrous tissue."

Fibroma from the palmar surface of the hand, apparent exciting cause of reflex (Jacksonian) epilepsy. Presented by Dr. CHARLES K. MILLS.

I am indebted to Dr. L. F. Flick for the opportunity of presenting this specimen, the patient from whom it was removed having been for a long time under his care.

M. S., æt. 15, when four years old, fell down-stairs from a height of five steps, striking on the right palm. The hand was not bruised or cut, but the child suffered great pain in it for several weeks. Six months after the fall, two little growths about the size of a pea made their appearance, one on the palmar surface of the wrist, over the position of the common tendon of the flexor sublimis digitorum, the other in the palm of the hand, over the tendon going to the index-finger, about one-third of an inch from the metacarpo-phalangeal joint. The tumor at the wrist was painful, and grew gradually for five years until it became as large as a hickory-nut. It was then treated systematically with liniments and bandaging, and in three years more disappeared. The tumor in the palm continued very slowly to increase.

Six months after the first appearance of the growths the child began to suffer from attacks of spasm, at first affecting chiefly the right hand. They recurred usually once in about ten days or two weeks. The spasms gradually grew worse; eventually the right arm and leg and the right side of the face would jerk. For the last ten years she has continued to have seizures, generally at intervals of a week or two, but sometimes oftener. The limbs and face of the right side have always been more affected by the spasm than the same regions on the left. The twitching has invariably begun in the fingers of the right hand, and has been preceded by pain in the palmar tumor. The patient, who has always remained conscious, as the attacks have come on would grasp her right hand with her left, or would call on some one else to do this. Chloral, bromides, and other antispasmodics have been used freely, but without any evident effect.

In February, 1880, she began to have a series of paroxysms much more violent than any she had before experienced. At first the attacks came only more frequently during the nights, especially after twelve o'clock. After a few days, however, they increased in number during the day also, until finally they recurred every two or three minutes day and night, ether, bromides, and other medicines having no effect. Menstruation now set in for the first time, and at once the convulsions ceased, after having continued as just described for two weeks. She grew stronger speedily, and for four months did not have another seizure. She now again began to have occasional fits. Menstruation was not well established.

Early in September, 1880, a second continuous series of convulsive attacks began. At this time, in addition to her dysmenorrhœal symptoms, her digestion was much deranged. I saw her first, with Dr. Flick, on the 15th of September, and since have seen her frequently both during and between her paroxysms. A curious feature has been that as soon as she would fall asleep an attack would come on, while during her waking moments she would often rest easy. She could sometimes control the spasms by force of will; and a smart slap with the hand would sometimes cause the attack to cease.

The following is a description of the usual character of the attacks, as determined from the notes of Dr. Flick, and from personal observation:

The distal phalanx of the ring-finger of the right hand was first flexed; secondly, a few spasmodic movements of flexion would occur in this finger; thirdly, the other fingers and thumb of this hand would begin to twitch convulsively,—the second phalanges would be flexed, the last extended; fourthly, the clonic convulsive movement would extend the right hand, forearm, and arm, and simultaneously the muscles of the lower part of the right side of the face would become affected with spasm, a tremor also appearing in the tongue during this period; fifthly, the right arm and leg would now become affected with a clonic spasm, causing them to assume positions of flexion, the head, neck, and body being drawn by the spasm, at the same time, to the right, a condition of pleurothotonus being, in fact, produced. The seizures would pass off with a very severe jerking movement of the right shoulder, and a renewal of the twitching of the muscles of the right angle of the mouth. These movements of the shoulder and mouth would sometimes occur only once, just before the close of the attack; more frequently, however, they would take place two or three times in succession. Occasionally the patient would bite her tongue during the paroxysm. She apparently was never entirely unconscious during an attack, no matter how severe it might be. During the height of the convulsion, if her hand was pressed too hard, she would manage to gasp out, "Don't!" or to make some other exclamation.

After trying bromides, morphia, etherization, blistering, etc., without avail, I advised the immediate removal of the tumor. On the 26th of September, Dr. S. W. Gross removed the growth, Drs. Hearn, Kirkpatrick, Flick, and myself being present at the operation. The tumor was found to be a firm, lobulated

mass, three-fourths of an inch long and about half an inch in each of its other dimensions. When it was first exposed, a small nerve-branch could be seen passing over its upper inner edge. It was somewhat firmly attached to that tendon of the flexor sublimis digitorum which goes to the index-finger.

The growth was placed for microscopical examination in the hands of Dr. Carl Seiler, who reported it to be a fibroma.

The following, in brief, is the history of the case for the four weeks which have elapsed since the operation. She has been kept absolutely without treatment for the spasms. She improved at once in her general condition. She has averaged a little less than one attack a day since. The right hand or arm has never been affected in any of these seizures, only a few of which have been severe.

Remarks.—I am inclined to look upon the spasms in this case as primarily, at least, reflex, the fibroma of the palm acting as an exciting cause. This seems probable for a number of reasons. (1) The spasms appeared after the fall and the development of the growths. (2) Before the removal of the tumor the spasm invariably began in the finger of the right hand, on the palm of which the growth was situated. (3) The spasms were usually of the nature of monospasms, or unilateral convulsions of the right side of the body. (4) The spasms became much less frequent and severe, and ceased to begin in the fingers of the right hand, after the operation.

The convulsive disease from which this child has suffered has all the characteristics of what has been termed "Jacksonian epilepsy," in honor of Hughlings-Jackson. By a "Jacksonian epilepsy" is meant a convulsive affection confined to a group of muscles, to a limb or to two limbs, or to face and limbs of the same side, and usually commencing in the same way. Consciousness sometimes is and sometimes is not lost. Unilateral convulsions are more likely to be associated with loss of consciousness than spasm confined to the face or to one limb.

Have we in a case like this any real morbid changes in the brain? Without doubt, I think, such changes have taken place. Post-mortem examination would probably reveal inflammatory changes of the cortex, most marked in the middle Rolandic region of the hemisphere. The presence of the tumor in the hand may, of course, be merely a coincidence, and we may have here in the arm-centre of the left side a tumor, cyst, tubercle, or other lesion, irritative in character and the primitive cause of the monospasm. Cases are on record corresponding in their main features, as regards the origin and progress of the spasmodic manifestations, with our case, and in which, after death, small cysts or tumors have been found in the motor zone of the convolutions.

Removal of left superior maxilla, left malar, nasal, lateral mass of ethmoid and pterygoid processes of sphenoid for tubular epitheliomatous pharyngeal polypus. Presented by Dr. C. B. NANCREDE.

Charles Muscavitz, aged 52 years, a Pole, was admitted into the male surgical ward of the Protestant Episcopal Hospital in the early part of September, 1880. He most positively asserted that he had noticed nothing until two months before coming to me, when his eye began to be protruded. When I first saw him his left eye was displaced outwards and upwards by a firm, hard mass, seemingly involving the internal angular process of the frontal bone, the nasal process of the superior maxillary, and the orbital plate of the same bone to a limited extent. There was no bulging of the infraorbital region, but, the finger being introduced into the mouth, a slight fulness with tenderness could be detected beneath the zygoma. The posterior portion of the hard palate was slightly depressed, while the soft palate was bulged downwards. By carrying the finger behind the soft palate into the pharynx a large, irregular, lobulated mass was detected, completely filling up this cavity, except perhaps towards its right moiety. The nasal process of the left superior maxilla and the nasal bones were pushed upwards and outwards by the extension of the growth into the left nasal chamber. Indeed, polypoid masses could be detected by both the eye and finger, completely filling the left nostril. I diagnosed a malignant pharyngeal polypus. After consultation with my colleagues, I determined to extirpate the growth with the involved bones. The patient having been first etherized, the Fergusson incision was made and the flap reflected. All hemorrhage having been arrested, chloroform was administered in the place of ether, and the operation completed in the ordinary manner, with a few exceptions presently to be mentioned. Owing to the failure of the bone-forceps to divide the zygoma, the whole malar bone came away, from some lateral motion in using the instrument. Only a part of the tumor came away with the superior maxilla, owing to its firm connections with the roof of the pharynx. The portions of tumor left after the removal of the upper jaw were torn away by the fingers or Fergusson forceps, or cut away with scissors. Owing to the able manner in which I was assisted by my colleagues, Drs. Forbes and Hunter, very little blood was lost. One unusual circumstance was the ease with which hemorrhage was arrested, owing to the fortunate circumstance of the stump of the internal maxillary artery projecting some half inch or more, thus admitting of its ligation. Only a very sparing use of the hot iron was requisite. The whole wound was wiped out with chloride of zinc. The case did well, with the exception of sloughing of the cornea, some two weeks after the operation, from secondary

implication of the nerve, either by inflammation or extension, perhaps, of disease into the sphenoidal fissure. Examination showed that the whole left superior maxilla, the left lateral mass of the ethmoid, part of the vertical plate of the same bone, the left nasal, the lachrymal, the left malar, and both left pterygoid processes of the sphenoid had been removed.

Microscopical Report, by Dr. J. H. C. Simes.—"The growth, upon microscopic examination, is seen to consist of epithelial cells, forming solid tubes or peg-like prolongations, which branch and anastomose with other similar prolongations. Between the tubes is a small amount of fibrous tissue infiltrated with embryonic cells. In some of the pegs the cells have arranged themselves in a concentric manner, forming, somewhat imperfectly, cell-nests or pearly bodies. This histological arrangement of elements would place the growth under the epitheliomata, and, according to Cornil and Ranvier, with the tubular variety of this class of tumors."

Polypous tumor of labia. Exhibited by Dr. H. F. FORMAD.

Dr. U. M. Beachly, of Meyersville, Pa., sent me this interesting tumor for examination, accompanied by the following history:

Removed from a married lady, aged 38, robust health, weight 210 pounds; eight children, all living. The tumor has been developing for four years. Never gave her much pain. It was attached by a pedicle to the right labia pudenda. The pedicle was two and a half inches in length and one-quarter inch in diameter, having a peculiar appearance, resembling the trachea of a small animal. The tumor when removed was two ounces in weight, in external appearance resembling a cauliflower growth, having an uneven surface, covered by a skin, consistency soft and elastic, and in color bright red. On one side of the tumor was a scab which bled freely when removed.

Upon microscopic examination, the tumor shows the structure of a lipomatous myxoma.

Dr. S. W. Gross said that such tumors were very rare, but that Virchow had delineated a pedunculated myxomatous tumor of the labium majus of much larger size than the one just presented by Dr. Formad, and that Paget refers to several examples.

Metastatic osteoid round-celled sarcoma of the skull, dura mater, and lower maxilla. By SAMUEL W. GROSS, M.D.

On the 27th of September, 1879, I amputated through the middle of the arm of a boy two years of age, on account of a periosteal osteoid round-celled sarcoma of the left ulna, which measured three inches and a half in length and two inches and a half in width, and began to develop at the age of three months. On dissection of the limb, four sarcomatous lymphatic glands, none of which exceeded the size of a large bean, were discovered along the line of the brachial artery above the elbow. In my comments upon the case before the Philadelphia Academy of Surgery, October 6, 1879,* I called attention to the fact that the ulna was rarely the seat of the disease; that the lymphatic glands were implicated in only 6.25 per cent. of the forty-five cases which I had analyzed; that the subject was the youngest on record; that the prognosis of these neoplasms was most unfavorable, since two-thirds of all patients die with metastatic deposits whether they are subjected to operation or not; and that the secondary growths were most common in the lungs, lymphatic glands, and the osseous system.

On the 25th of June, 1880, the child was brought to me with a densely-hard tumor of the right temporal region as large as the half of an ordinary orange. This continued to increase, but the child had been enjoying tolerable health, the only troubles having been complaints of the weight of the head and difficulty in mastication on the right side, on account of a tumor of the right ramus of the lower jaw, until the night of October 25, when it was seized with convulsions, which were of short duration and very frequent, at least twelve having occurred in thirty minutes. These continued, at more prolonged intervals, until noon of October 27, when death ensued after a violent paroxysm.

For the following notes of the post-mortem examination, which was made twenty-two hours after death, I am indebted to Dr. Ames, resident physician in the Jefferson Medical College Hospital:

"Rigor mortis well marked; extreme emaciation; lower extremities œdematous; stump healthy. On the right side of the head there was a tumor, soft on its surface but hard at its circumference, which was limited above by the temporal ridge, and extended one inch below the condyle of the lower jaw. Its basal circumference was sixteen inches and a quarter, and it measured nine inches from the outer angle of the eye to the posterior portion of the parietal bone. The temporal veins were enlarged, and the skin was discolored just behind the ear. A second tumor was situated in the ramus of the right inferior maxilla, and measured three inches from the outer angle of the eye to the angle of the jaw, and three inches and a quarter from the angle of the mouth to the condyle of the jaw. Upon removing the firmly-adherent scalp, a tumor as large as a hickory-nut was discovered at the junction of the parietal and occipital bones, and was connected, through what seemed to be the posterior fontanel, with the interior of the skull. Another growth, of the same dimensions, was seated at the upper and posterior junction of the temporal and parietal

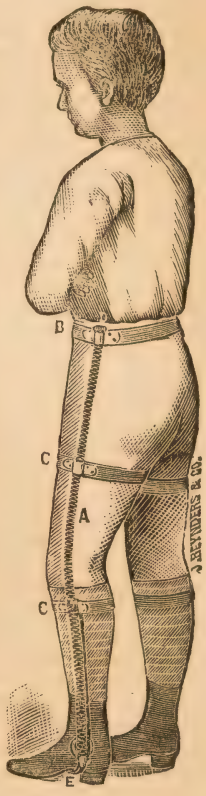
* Medical Times, July 3, 1880, p. 500.

bones. The left parietal, temporal, occipital, and frontal bones were of a dark-blue color, and the right parietal bone overlapped the frontal bone for a quarter of an inch. All the bones were thin and very brittle. The dura mater was congested, and an ante-mortem clot three inches long occupied the longitudinal sinus. The arachnoid was normal, but the pia mater was deeply congested. The substance of the brain was very soft, and its veins were engorged. A tumor three inches long, three and a half inches wide, and two inches thick occupied the middle fossa of the skull, and the corresponding lobe of the brain was almost diffluent. The tumor itself was firmly attached to the inner surface of the dura mater, and sent prolongations through that membrane to another tumor of about the same size growing from its outer surface. The large tumor of the right temporal bone appeared to originate in its medulla."

All of the smaller tumors are of a brain-like consistence, and do not appear to be the seat of ossific or calcareous deposits. The large tumor, however, is precisely similar to the primary growth of the ulna, and is beset by delicate spicules of bone which radiate from its centre to its circumference. As the specimens have been removed so short a time, there has been no microscopical examination of their minute structure; but I have no doubt that they will be found to be of the same nature as the primary tumor, which consisted of small round-cells contained in a finely-granular matrix.

THE SPECIFIC AGENT OF TYPHOID FEVER.—Prof. Klebs, of Prague (*Brit. Med. Jour.*, vol. ii., 1880, p. 629), believes that he has discovered the micro-organism which constitutes the specific agent of typhoid fever, and develops his views in a paper entitled "Der Ileotyphus eine Schistomycose," published in the *Archiv für Experiment. Pathologie*, Bd. xii. p. 231, 1880. Prof. Klebs has for a long time, assisted by his pupils, been making researches in this direction. He writes that he has been able to find, at the necropsy of twenty-four persons carried off by dothinenteritis, microbes in various organs,—in the intestinal mucous membrane, in the thickness of the cartilages of the larynx, in the pia mater, in the foci of lobular pneumonia, in the mesenteric ganglia, in the parenchymata of the liver, and generally diffused in the organs which showed the most decided lesions. These micro-organisms showed themselves in the form of rods, about eighty micrometers in length and 0.5 to 0.6 micrometer in thickness. They have been constantly observed in the bodies of dothinenteric patients since the attention of Prof. Klebs was drawn to the subject, and they are always absent from the organs, and especially the intestines, of subjects who have died from any other disease than typhoid.

PHILADELPHIA ACADEMY OF SURGERY.



MEETING OF NOVEMBER 1, 1880.

The President, DR. S. D. GROSS, in the Chair.

CLUB-FOOT, SPLINT FOR EARLY TREATMENT OF. BY DE F. WILLARD, M.D.

THE splint here shown is one devised by Dr. Doyle, of Syracuse, and while it does not, to my mind, act sufficiently upon the medio-tarsal articulations to make it serviceable in bad cases of deformity, yet its principle is so simple and perfect in action that I deem it of great advantage in a certain number of cases.

It consists of a pelvic band buckled about the body and prevented from turning by shoulder-straps. From this extends a steel spiral or "flexible shaft," as it is called by machinists, along the outside of the leg, to be fastened into the shoe. This is three-eighths of an inch in diameter, and is held in position by straps encircling the thigh and leg. From the calf to the foot additional strength is secured by a steel upright riveted to the sole of the shoe and jointed at the ankle.

A. Spiral steel spring.
B. Belt around the hips.
C. Loops to hold spring in place.
D. Set-screw by which tension is regulated.
E. Plate by which the spring is fastened to the shoe.

Where but one spring is worn, a strap should be thrown across the opposite shoulder to prevent the belt from shifting.

In applying the apparatus the pelvic- and thigh-bands are secured, when, if the case be one of varus, the shoe is rotated *once* inward; the foot is then placed in it and fastened by lacing. It will at once be seen that the constant tendency of this spring will be to uncoil itself into its original position, and in doing this it must carry outward the toes. In valgus the action would be reversed. It is a force exerted gently, constantly, and "coaxingly," awake and asleep, and if increased power be required the shoe can be rotated twice or three times before it is applied to the foot.

A great advantage obtained by its use is the fact that it in no wise interferes with either the motion of the leg or the action of any muscle, save of the ones which it is intended to antagonize. Its tendency to straighten

itself as a whole would, in a slight degree, raise the anterior part of the foot, and to that extent benefit even an equinus.

As I have said, it does not act with much force upon the medio-tarsal joints; yet its applicability to very young children is greatly in its favor, as it can thus be used as a continual assistant to manipulations. As is well known, the majority of cases of congenital varus can be cured by manipulation and stretching, but as the hands of the surgeon cannot be always in service, and as the mother will not do this more than fifteen minutes during the day, it will be seen that a force acting steadily through the remaining twenty-three and three-quarter hours will prove no mean accessory, even though it be not equal to the hand of the surgeon or nurse. Such a splint applied even during the first week of the child's life could do no harm, and if nickel-plated the urine would have but little effect upon it. By the time that three months have passed, and the child is ready for tenotomy, it will frequently be found that no operation is necessary save section of the tendo Achillis.

For pigeon-toed cases this spiral rotator would be most perfect in its action, and the principle could be employed with advantage on any limb which is deformed by rotation upon its long axis. The inventor has used it for torticollis,* and also employs it after division of tendons in varus and equinus. I like the mode of action of the spiral, and shall certainly give it a full trial. If it could be secured firmly to the upper part of the leg, its rotating effect upon the foot would be exerted to a much greater extent; in its present form both hip and knee are influenced.

Dr. T. G. Morton believes that in very young children talipes varus depends more on the bones than on the muscles, and hence he is accustomed to press the tarsal bones into position with his thumbs at once. Sometimes ether is required during this procedure. This method for very young children he has found very satisfactory. After the bony deformity has been rectified, the mother is directed to manipulate the foot frequently and the surgeon sees that the parts are properly everted by manipulation. Finally, after the varus has been cured, the condition of equinus (when the child begins to walk, say, when a year old), should it exist, is remedied by tenotomy. The spiral rotator of Dr. Doyle would hardly have sufficient power to force even the bones of infancy into the proper position.

COMPLETE EXCISION OF THE ELBOW FOR GUNSHOT INJURY, WITH GOOD RESULT.

Dr. R. J. Levis presented to the Academy a case of extensive excision of the elbow-joint, with the following history. A burglar, while entering premises, was shot by a gun set as a trap, and the entire charge of small shot and wadding entered the back of elbow. The upper extremities of the radius and ulna were comminuted, and the lower end of the humerus was split vertically and repeatedly perforated by the shot. The large arterial and nerve trunks were uninjured, and it was determined to make an effort to save the limb by making a complete and extended excision.

The section of the lower end of the humerus, which was exhibited, measures three inches in length, and the comminuted radius and ulna were removed to about a similar extent. The medullary cavity was invaded by the section. It is now seven weeks since the operation, and the parts have cicatrized. The motions of the hand are strong and complete, but at the place of the excision there remains a flail-like union, over which the patient has at this time very little control. It seems probable, however, that as the cicatrix contracts and solidifies the bond of union will shorten, become more rigid, and bring the ends of the divided bones more nearly into apposition, so that the muscles of the arm can resume control of the motions of flexion and extension. If this should fail from want of fixation, some artificial encasement supporting the new joint may be available in regaining the usefulness of the extremity.

In cases of complete excision of the elbow where there is a loose flail-like bond of union, some patients attain the power of controlling its movements by contracting all of the muscles which act on the joint, thus bringing the bones into apposition and producing rigidity, and then the excessive action of either flexors or extensors can effect a corresponding movement.

In excisions of the elbow it is important that the ulnar nerve shall be turned out of its groove behind the internal condyle without being divided or wounded. Experience shows that such injury of the ulnar nerve is followed not only by loss of power of the structures to which it is distributed, but there occurs wasting of parts beyond those which are supplied by that nerve, due probably to influences through its peripheral connection with other nerves.

The elbow seems more amenable to successful excision than any other of the larger joints of the extremities, to which the comparatively superficial position of its posterior surface and the narrowing of bones immediately above and below their articular surfaces seem to conduce. The invasion of the medullary cavity of the humerus does not seem to invalidate success.

Dr. T. G. Morton thought he had never seen a more discouraging case for excision, since the whole outside of the elbow was blown off and so much tissue had to be removed. The free drainage from behind was probably an important point in the subsequent result.

* New York Medical Record, June, 1880.

TWO CASES OF COMPOUND COMMINUTED FRACTURE OF THE ANKLE, WITH LUXATION; RECOVERY WITHOUT OPERATION.

These cases were presented by Dr. T. G. Morton, who gave the following histories:

Anton W., aged 24, a coppersmith, was admitted May 4, 1880, with a compound comminution of the left tibia, with compound luxation of the ankle. In the foundry in which this man was working, a swinging copper kettle fell from its chain, striking him upon the outer side of the left ankle, causing the above injury. The open wound was three and a half inches long, running across the inner malleolus, evidently caused by the end of the tibia, which was thrust through the skin; the articulating surface could be seen; the heel was thrown far backwards and upwards, and the foot was also everted, but the fibula was intact. Loose fragments of bone could be felt in the wound, and there was not much bruising of the parts.

Dr. Hunt removed two fragments of the articulating surface of the tibia, washed out the joint with carbolized water, tied two small vessels, introduced drainage-tube, and covered the vent with charpie wrung out of carbolized oil. He then suspended the limb loosely in a fracture-box, having applied plaster bandage from the knee to the toes, allowing vent for tube.

May 7, plaster bandage had to be cut on account of swelling. There was free suppuration, with much redness and joint swollen.

June 12, bran dressing applied, and, as pus had bagged and collected behind the outer side of the ankle, an opening was made.

July 2, leg removed from bran; wounds healing. At the present time the man can walk very well, and shows a good recovery without operation.

The second case, Thomas D., aged 50 years, was admitted to the Pennsylvania Hospital, June 28, 1880, with compound luxation of tibia and comminuted fracture of fibula, with the joint freely opened. During a street-brawl he was thrown down with his left foot caught in a cellar-door, and fell sidewise while the foot was thus entangled. The tibia was protruding one and a half inches through a wound over the malleolus three inches in length. There was considerable hemorrhage, though the main vessels were uninjured.

The tibia was reduced, and irrigation with a weak solution of permanganate of potassium commenced as the line of treatment. This was continued for more than two weeks, when a carbolized-oil dressing was substituted. Subsequently a few fragments of bone were removed from the outside of the limb, evidently from the fibula.

The patient was discharged cured, with a good limb, during October, and is presented for the examination of the Fellows of the Academy.

Dr. William Hunt said that the first case was an exception to the dictum given at the time the paper of Dr. Brinton, advising amputation, was read. He at first intended to amputate, but had decided to try conservatism, and the patient recovered. The man nearly died, however, during the course of the treatment, and it may be that this case, by inducing us to attempt conservative surgery in other instances, will cause numerous deaths.

Dr. C. T. Hunter mentioned two similar cases under his care at the University Hospital, where cure resulted without operative interference. They were worse in appearance than the first case presented by Dr. Morton. If the vessels are intact he believed that it was usually well to make conservative efforts without operation of any kind, since the improved methods of treating such cases, by antiseptic dressings and drainage, allow much to be done in this way that formerly was impossible. He mentioned also a case of gunshot wound of the knee followed by cure without operative interference. The general plan of treatment in such instances is by immobility, which is the most important point of all, through drainage and irrigation. Immobility cannot be obtained by the fracture-box, but the fixed dressing does accomplish it.

Dr. R. J. Levis was of the opinion that the non-operative plan of managing such injuries was opposed to the usual experience of surgeons.

PULSATING TUMOR SITUATED BELOW THE BEND OF THE ELBOW.

Dr. R. J. Levis introduced a patient who presented a pulsatile tumor situated below the bend of the right elbow. The history was indefinite. There was less pulsation on the radial side of the arm than on the ulnar. The radial pulse was perceptible; the ulnar was not. Pressure on the brachial artery arrested pulsation in the tumor, but did not render the diagnosis much clearer. For two weeks the patient had had a great deal of pain in the part, which showed considerable superficial redness. The case seemed like an aneurism involving the ulnar artery bound down by deep fascia, but might be malignant disease of great vascularity, especially as spontaneous aneurism in this locality is almost unknown. The man also had a large enchondromatous tumor attached to the thorax over the cardiac region.

The Fellows were asked as to their experience of aneurism in this situation, but none of those present had ever seen aneurismal dilatation in this region except as the result of traumatism.

Dr. William Hunt expressed his opinion that spontaneous aneurism here is rare, because the brachial artery slips laterally when flexion occurs at this joint. The artery rolls or slides inwards nearly an inch, and thus avoids being pinched. The popliteal artery

has no such lateral motion, and is frequently the seat of aneurism.

Dr. S. W. Gross believed the case, on superficial examination, to be a round-celled pulsatile sarcoma.

(To be continued.)

GLEANINGS FROM EXCHANGES.

Treatment of Fibroid Tumors of the Womb by Ergot and Chloride of Ammonium.—Prof. Goodell, in a paper read before the Medical Society of the State of Pennsylvania, says, "There is no question of the occasional benefit derived from the persistent use of ergot, which, by constringing the uterine walls, cuts off the blood-supply of the fibroid. But, while I have repeatedly seen the tumor grow much smaller under its use, I have also seen the remedy do more harm than good. Ergot is best administered hypodermically, and preferably in the subumbilical region of the abdomen, where it gives least pain, and where its skin-stains are best concealed. Bonjean's purified extract of ergot, in the proportion of fifty grains dissolved in three hundred minims of distilled water, is for this purpose a very trustworthy preparation. One or two hypodermic syringefuls is the dose, which should for several weeks, or even months, be deeply injected once every day." In one case, where the patient dreaded any surgical interference, and even objected to hypodermic injections, Dr. Goodell decided to try, by the mouth, a combination of ergot and ammonium chloride. She daily took from twenty to forty drops of the former, and ten grains of the latter. After eleven months of this treatment she came to see him in last March, and he was astonished at her improved appearance. Her hemorrhages had wholly ceased, and so reduced in size was the fibroid that, to discover it, careful examination was needed. Yet, on the other hand, ergot, however administered, will occasionally not only do no good, but will greatly increase the hemorrhages, especially when the tumor lies under the mucous coat of the womb and projects into its cavity. Then, again, there are peculiar idiosyncrasies which cannot bear ergot in any form or in any dose. Such persons are either greatly nauseated by its use, or they complain of intolerable headache, and the remedy must be withheld. Further, the use of ergot is not wholly without danger. Through the squeezing which the tumor gets from the ergotic contractions of the uterine walls necrosis may take place, and this, while curative, is liable to cause blood-poisoning through absorption of putrilage. Twice has Dr. Goodell met with a metro-peritonitis set up by the violent contractions of a womb made vulnerable by the presence of a growth in its wall. In one of these cases, that of a multiple fibroid, the issue was fatal. Despite these drawbacks, however, especially when combined with ammonium chloride, it is so efficient an agent in mitigating the more exacting symptoms arising from a uterine fibroid that its use should always precede every other treatment.

Radical Treatment of Fibroid Tumors of the Womb.—In the paper above quoted, Prof. Goodell says, after discussing the use of ergot, that where ergot, together with its staunch ally, ammonium chloride, has been tried and found wanting, the radical or surgical treatment must be brought into use to remove these growths. He adds that, having performed enucleation by avulsion fourteen times, he can speak in positive terms of its value. His method of operating is as follows. First, seize the tumor with a strong fenestrated polypus-forceps, or with a volsella-forceps whenever the growth is too smooth and too glib to be securely held by the former instrument. He prefers the fenestrated forceps, because, being without teeth, it is not only safer than the volsella, but it does not have to be opened so widely, and, therefore, needs less room. The tumor being firmly held, the loop of a wire écraseur is slipped over the handle of the forceps, and then bent backward towards the operator, so that the beak of the écraseur shall first enter the uterine cavity. When the beak touches the fundus of the womb, the wire is coaxed up beyond the claws of the forceps, and as much higher up as possible. The slack of the wire is next drawn in, and its free end secured to one of the cross-bars of the écraseur, so that a half-crushing and a half-cutting movement shall be secured. The mucous coat alone is now cut through as flush with the uterine wall as possible. The fibroid is then wrenched from its bed, by traction and by a twisting movement made both with the écraseur and the forceps, while firm suprapubic pressure is kept up by the hands of an assistant. Sometimes the seized portion will break off. Then the portion left behind must be caught, noosed, and treated, if possible, in precisely the same manner.

Twice has he been foiled in trying to remove the whole tumor in this way. In these cases the projecting portion of the fibroid was shaved off flush with the wall of the womb. But the portion left behind was in a few days so pushed out, or enucleated, by the uterine contractions as to enable him to remove it by a second operation. Subperitoneal fibroids are not amenable to any radical treatment per vaginam. If pedunculated, they can be treated like ovarian tumors, by laparotomy. Sometimes they are removable by enucleation through an abdominal incision. In one case Dr. Goodell obtained perfect success by removing the ovaries and thus artificially bringing on the change of life.

Indications in Opium-Poisoning.—Dr. Kane, in a chapter devoted to the subject in his work on "The Hypodermic Injection of

Morphia," speaks at length of the treatment of opium narcosis. He tabulates all the remedies usually found of benefit in these cases, and gives the indications for treatment, as follows:

To aid to establish respiration.
To stimulate the heart.
To produce general stimulation.
To counteract soporific effects.
To produce diuresis.

He believes opium and belladonna mutually antidotal in certain particulars only, and cites the experiments and conclusions of many well-known writers upon the subject. The value of coffee, or its active principle, is also discussed.

A Case of Poisoning by Duboisia.—E. L. Holmes, of Chicago, reports the following case (*Chicago Med. Jour. and Exam.*, November, 1880). A patient at the Illinois Charitable Eye and Ear Infirmary, during convalescence after Graefe's operation for cataract, was provided with a small bottle of sulphate of duboisia, gr. j to ʒj, in place of sulphate of atropia, which caused considerable conjunctival inflammation. On the 27th of April, about nine o'clock in the evening, he took by mistake a "teaspoonful" of the solution. It cannot be determined whether the teaspoon was quite full. The patient at once informed other patients near him that he had taken the wrong solution, but concluded to await the result before reporting to the nurse. In about ten minutes there was dryness of the throat, and in half an hour a peculiar sensation in the legs, then in the thighs, arms, and other parts of the body, as if they were asleep. At the end of three-quarters of an hour, or more, the patient could scarcely talk or stand. Strange to say, not till this time did it occur to the patient or those around him to call the nurse. An active emetic was at once given, with the apparent effect of entirely relieving the stomach of its contents. Without delirium the patient rapidly passed into a state of unconsciousness, and remained in this condition till about five o'clock in the morning. He complained for two days of muscular weakness in the legs and arms, and especially noted a peculiar jerking action of the muscles of the arm in extending the hand to grasp a glass or other object. Dr. Holmes saw the patient at midnight. He was lying quietly, breathing naturally, but in a stupor from which he could not be aroused. The face was not specially flushed, although the mouth and tongue were remarkably dry. The temperature, as determined by the thermometer, had been normal. The pulse varied from 108 to 112. Some time previous to this, before unconsciousness became quite complete, the patient made efforts to sit up in bed. The pulse always fell to 80 when the patient sat up, and increased on lying down. No other symptoms were noticed. An ounce of brandy was given through the night. Morphia was not given as an antidote.

Double Cystic Kidney with Renal Calculi.—From a Danish source the *British Medical Journal* of October 30, 1880, takes the report of a man 37 years of age, who had first voided a renal calculus in 1871 and another in the autumn of 1872. Since that time his health had been good, but sometimes he had a feeling of weight in the loins and discharged a little gravel. On July 1, 1879, he took cold, and soon noticed that the daily quantity of urine diminished, until the 8th, when there was suppression. He was admitted to the hospital on July 9; his bladder was then empty. In the course of the next night he voided about seven ounces of urine with his stools. He complained only of soreness in the region of the right kidney. The urine could not be examined until the 15th, when it was found to contain much albumen. On that day symptoms of uræmia set in, and he died on the 16th. At the necropsy the kidneys were found to be both greatly enlarged, the left, however, more than the right, and both presented almost complete cystic change. The renal parenchyma remaining in the interspaces between the cysts had a yellow-gray turbid appearance. The pelvis of the right kidney was much dilated and contained a large nodulated calculus, the lower part of which was rounded and covered in the orifice of the ureter, which was dilated. The left ureter, at a distance of about two inches from the kidney, was completely blocked up by a calculus of moderate size; below this the canal was completely strictured by indurated connective tissue, scarcely allowing the passage of a fine sound. Above the stone the ureter was dilated, and the pelvis and calices especially were greatly expanded.

Dr. Axel Key, who examined the specimens, thinks it remarkable to find such extensive changes in the kidneys of a person who had enjoyed relatively good health up to a fortnight before his death. He regards the cystic change as having been principally congenital, and as having no connection with the formation of the renal calculi and the consequent obstruction to the flow of urine. The renal parenchyma, which was found between the cysts, had been sufficient for the function of the kidneys. When the renal concretions began to be formed, hydronephrosis was gradually developed, and in connection with it a chronic nephritis with interstitial and parenchymatous changes, which went on for a time without producing any marked disturbance, until at last an acute exacerbation set in and rapidly caused death.

Atropia in Chloroform Anæsthesia.—A correspondent of the *British Medical Journal* (October 30, 1880), referring to a previous communication on this subject by Mr. Shäfer (see *Medical Times*, November 20), says that the subject has been for some years worked out by Professor T. R. Fraser, of Edinburgh,

who has shown atropia to be a cardiac stimulant, advisable when chloroform is to be given. It stimulates the heart, not only indirectly, by lowering the conductivity of the cardiac terminations of the vagi, and thus, of course, diminishing their inhibitory power, but also directly, by stimulating the intramural motor ganglia of the heart, and possibly, also, by raising the excitability of the accelerator nerve to the heart from the cervical sympathetic ganglia, and perhaps it may even stimulate the cardio-motor centres in the medulla oblongata. Dr. Frazer considers it advisable to combine with the atropia a little morphia, say $\frac{1}{120}$ to $\frac{1}{60}$ grain of sulphate of atropia and $\frac{1}{12}$ to $\frac{1}{8}$ grain of acetate or hydrochlorate of morphia. These are injected about fifteen or twenty minutes before the administration of chloroform is begun, and by this means (1) not only is the patient in a less nervous state when the inhalation is commenced, but (2) less chloroform is required, and (3), moreover, a very objectionable evil is got rid of, or, at all events, ameliorated,—viz., the emesis which is apt to occur with chloroform. In the cases in which the correspondent of the *British Medical Journal* has seen this method followed there has been no vomiting whatever, although in some the inhalation was considerably prolonged.

The Treatment of Tapeworm.—At a recent meeting of the New York Pathological Society (*New York Medical Record*, November 20, 1880) Dr. Tauszky described his treatment as follows: Three ounces of pomegranate-root are soaked for twenty-four hours in eight ounces of water. This is then boiled down to three ounces, to which are added three ounces of the ethereal extract of male fern, one and a half drachms of sulphuric ether, two drachms of fluid extract of valerian, one drop of croton oil, and one and a half ounces of honey. The patient then abstains from all food save herrings and onions, and also from water. The dose of the medicine given is one-third every half-hour. As soon as the patient feels intestinal contractions or colic, whether this is after the first, the second, or the third dose, one ounce of castor oil is administered hourly in cold black coffee, without sugar, until the worm is expelled. In case the vermicide mixture causes nausea, lemonade, ice pills, or strong, cold black coffee, without sugar, relieves it. The preparatory treatment is a dose of castor oil forty-eight hours before taking the worm medicine, so as to empty the bowels thoroughly of fæces. Milk diet exclusively for twenty-four hours following the laxative, and the twenty-four hours before taking the mixture. The patient abstains from food and drink, except that he occasionally takes a little salad, made up of salt herring, onions, and garlic. [If the doctor can get him to take such a mess, which we much doubt.—Ed.] After the worm is expelled, mucilaginous food only is taken for a day or two, and a starch and laudanum enema in case of tenesmus.

Paralysis of Cranial Nerves in Congenital Syphilis.—At a recent meeting of the Pathological Society (*Lancet*, vol. ii., 1880, p. 657), Mr. Nettleship brought forward a living specimen, a girl of stunted growth, having distinct evidence of congenital syphilis. She was affected on the right side with partial anæsthesia of the parts supplied by the first and second divisions of the fifth nerve, complete paralysis of the sixth nerve, and partial of the third and fourth. There was also opacity of the cornea, old iritis, choroiditis, and probably retinitis; it was impossible to tell the exact condition of the optic nerve, but vision was fair. The right eye was apparently markedly smaller than the left, which might perhaps be connected with an obvious asymmetry of the bones. There was old keratitis and choroiditis on the left side, but no paralysis. He was unable to say whether the seat of the lesion was in the orbit or the cranium; there were no symptoms of disease in either. The President, Mr. Hutchinson, stated that there had been many recent additions to our knowledge of brain and nerve disease in inherited syphilis. He himself had published two or three cases of ocular paralysis, but it was bilateral, giving evidence of a central origin: he had never met with a case where there was distinct evidence of pressure on the trunks of nerves.

Poisoning with Homœopathic Granules of "Nux."—Dr. Gaspar Griswold (*New York Med. Record*, vol. ii., 1880, p. 374) gives the case of a patient who was accustomed to take five homœopathic granules of "nux" repeated two or three times for sick-headache. On one occasion, however, she went beyond this dose, and took fourteen granules, taking it five times—the dose amounting to seventy granules in all—in the course of an hour and a half. Alarming symptoms of strychnia-poisoning supervened, which were finally overcome and the patient recovered.

Perforation of Membrana Tympani by Ascaris Lumbricoides.—Dr. Lewis W. Reynolds (*Lancet*, vol. ii., 1880, p. 653) was called to see a little girl who two weeks before had vomited several round-worms and about the same time suffered severely from dyspnœa and intense pain in the chest and abdomen. Shortly before the doctor's arrival the patient had vomited two worms, and three more were discharged from her nostrils, her nose bleeding first for three hours. Four grains of santonin powder were prescribed, to be taken at bedtime, after taking which four worms were passed per rectum for the first time. Three or four hours after taking the second powder, and having previously suffered from an intense earache, a neighbor discovered a worm protruding from each ear and both ears bleeding; the same day three others came away

from the ears, others were discharged from the ears and also from the bowels, seventy-four in all. The patient afterwards showed excoriation of either meatus and a large perforation of both membrana tympani. She finally recovered.

INFLUENCE OF ALCOHOLIC BATHS ON THE PERSPIRATORY FUNCTION OF THE SKIN.—Dr. S. Wassalieff found that, after the skin had been thoroughly rubbed with alcohol, hot baths induced much more profuse perspiration, exceeding sometimes four and five times the amount of water lost, without previous treatment with alcohol. Hence the two processes should always be combined when there is indication for extraction of a considerable quantity of water through the skin. Dr. Wassalieff explains the action of alcohol by an irritation of the sensitive and perhaps also of the secretory nerves of the skin, and also by the removal of fat from the surface of the skin and the glandular pores.—*New York Medical Record;* from *Wratch.*, 1880, No. 13.

FATTY TUMOR OF THE LARYNX.—At a recent meeting of the Pathological Society (*Lancet*, vol. ii., 1880, p. 656) Mr. Sydney Jones showed a fatty tumor as large as a Tangerine orange, with a pedunculated attachment to the right aryteno-epiglottidean fold. It was met with in a man forty years of age. On opening his mouth, nothing abnormal was seen, but when he gave a peculiar gulp the tumor was brought up and lay on the dorsum of the tongue. It was removed by freely dividing the mucous membrane of the pedicle and tearing it out. A small cyst was found in it.

PRURITUS VULVÆ.—Dr. Tauzsky recommends the following (*New York Medical Record*, vol. ii , 1880, p. 387):

℞ Pulvis acaciæ, ʒii;
Bals. Peruvian., ʒi;
Ol. amygdalæ, ʒiss;
Aquæ rosæ, ʒi.—M.

Apply freely with a camel's-hair brush eight or ten times a day to the itching part.

MISCELLANY.

UNIVERSITY OF PENNSYLVANIA.—We learn that the trustees of the University contemplate using the chance afforded them by the interregnum in the line of provosts to make some organic changes in the duties of this office and that of vice-provost. For many years the vice-provost has had no duties of moment, or only in the absence of the provost; but meanwhile the duties of the provost have multiplied, so that it has become desirable, in electing a gentleman to fill this place, to assign to the vice-provost, under the authority of the provost, many of the details of administration, and to leave to the provost certain work which will not necessitate his giving to it most of his time, and will thus enable the trustees to select a competent presiding officer out of the ranks of the learned professions. Under this arrangement the provost would preside over trustee meetings and sit on important committees. He would interest himself with the general policy of the university, with the inter-relations of its schools, and foster and extend its relations to the State and city, as well as on all social occasions act as its representative. Such labors would not be inconsistent with the work of a profession, so that we hope soon to learn that the trustees have succeeded in finding among us some worthy representative both of our State and of the alumni of the school. The new appointee will be in reality a chancellor, and it is said that this change of title was at one time contemplated; but it was deemed best that the old and honored title of provost should be retained.

THE LAW OF SLANDER AS APPLIED TO PHYSICIANS.—Mr. W. H. Whittaker has in a recent number of the *American Law Register* of this city a very learned paper upon the above subject, from which we extract the conclusions:

"The question still remains, when do the misrepresentations of a physician's practice in a particular case warrant the presumptions of damage? It is allowed that slanderous words alleging gross ignorance generally, or such ignorance or thorough incapacity as unfits him for the proper exercise of his profession, are actionable *per se*. To say of a physician, 'He is a quack' (Pickford *vs.* Gutch, Dorchester Assizes, 1787); or, 'He is an empiric and a mountebank' (Vin. Abr., Act. for Words, S. a. 12); or, 'He is a quack; if he shows you a diploma it is a forgery' (Moises *vs.* Thornton, 8 Term Rep., 303); or, 'He is no doctor; he bought his diploma for fifty dollars' (Bergold *vs.* Puchta, 2 Thomp. & C., N. Y., 522); or, 'He is a drunken fool and an ass, and never was a scholar' (Cawdrey *vs.* Tetley, Godb., 441); or, 'He has killed six children in one year' (Carroll *vs.* White, 33 Barb., 615); or, 'It is a world of blood that he has to answer for in this town through his ignorance. He was the death of J. P. He killed his patient with physic' (Tutty *vs.* Alewin, 11 Mod., 221); or, 'I wonder you had him to attend him. Do you know him? He is not an apothecary; he has not passed any examination. He is a bad character; none of the medical men here will meet him. Several have died that he has attended to, and there have been inquests held upon them' (Southee *vs.* Denny, 1 Ex., 196). In all these cases it has been held that damages are inferable without proof; but to say of a physician, 'He is so steady drunk that he cannot get business any more' (1 Ohio, 83, n.); or, 'He is a twopenny bleeder' (Foster *vs.* Small, 3 Whart., 138); or to charge an allopathic physician with having met homœopathists in con-

sultation, and that in the opinion of the profession it was improper to do so, and against etiquette; and, further, that in the opinion of the profession it was disgraceful to meet a homœopathist in consultation (Clay *vs.* Roberts, 8 L. T., N. S., 397); or to charge him with adultery, not necessarily touching him in his profession, without showing that it was connected with his profession (Ayre *vs.* Craven, 2 Ad. & E., 2), have been held not actionable *per se*.

"While the authorities are generally agreed as to charges of gross ignorance or incapacity in the exercise of the duties of the physician, it is not easy to determine what words are actionable in themselves in special instances. In analogous and even in precisely similar cases, the courts are divided. Where the words were, 'He killed my child; it was the saline injection that did it' (Edsall *vs.* Russell, 4 M. & G., 1090); or, 'He has killed my child by giving it too much calomel' (Johnson *vs.* Robertson, 8 Porter, 486), they have been held actionable *per se*. And, on the contrary, the words, 'He has killed his patient with physic' (Poe *vs.* Mondford, *supra*); or, "In my opinion the bitters A fixed for B were the cause of his death' (Jones *vs.* Diver, 22 Ind., 184); or, 'He gave my child too much mercury, or made the medicines wrong through jealousy, because I would not allow him to use his own judgment' (Edsall *vs.* Russell, *supra*), have been held not actionable in themselves.

"In the examination of these cases, it will be found that where the physician is charged with killing his patient, the words have been held actionable on account of the imputation of crime which they import, and the only case in which such language has been held not actionable is that of Poe *vs.* Mondford, of an early origin.

"How such words necessarily import the crime of murder or manslaughter, in the absence of any expression of intention, is not quite clear. . . . Perhaps it would be more fatal to resort to legal proceedings in any case. If the physician does, he is compelled to show special damages, for none will be inferred. This alone would cause many to hesitate before bringing an action. The difficulty attendant upon proving damages, the length of time intervening between the publication and consequences of a slander, would deter many from the prosecution of the slanderer.

"As the cases now stand, one may bring almost any charge of misconduct against a physician in a particular case, without subjecting himself to an action for damages *per se*, provided it does not come within the category of a statutory crime or impute to him general incapacity."—*Cincinnati Lancet and Clinic*.

A Mycological Serenade.—The following verses, by Mr. Wilson, North Kimmundy, Aberdeen, were read at the dinner of the Cryptogamic Society, held during its meeting in Glasgow:

To Clara Marchella Deliciosa.

O lovely Clara, hie with me
Where Cryptogams in beauty spore,
Corticiums creep on trunk and tree,
And fairy rings their curves restore;
Mycelia there pervade the ground,
And many a painted Pileus rear,
Agaric rend their veils around
The Ranal overture to hear.

Where gay Peziza flaunt their hues,
A microscopic store we'll glean,
To sketch with camera the views
In which the Ascus may be seen.
Beneath our millimetric gaze
Sporidia's length will stand revealed,
And eyes like thine will trace the maze
In each Hymeneum concealed.

Æstivum tubers we shall dig,
Like Suidæ in Fagian shade,
And many a Sphæria-sheltering twig
Will in our vascula be laid.
For hard Sclerotia we shall peer,
In barks and brassicaceous leaves,
And trace their progress through the year,
Like bobbies on the track of thieves.

While sages deem Solanum sent
To succor Homo's hungry maw,
We'll prize it for development
Of swelling Peronospora.
We'll mount the Myxogaster's threads
To watch Plasmodium's vital flow,
While Capillitia lift their heads
Generic mysteries to show.

I'll bring thee where the Chanterelles
Inspire a mycologic theme,
While Phallus in the shadow smells
And scarlet Amanita gleam;
And lead thee where McMoorlan's rye
Is waving black with ergot spurs,
Where many a Trichobasian dye
Gives worth to corn and prickly burs.

And when the beetle calls us home
We'll gather on our lingering way
The violaceous Insolome
And russet Alutacea;
The brown Boletus edulis
Our fishing-baskets soon will fill;
We'll dine on fungi fried in bliss,
Nor dread the peck of butcher's bill.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM NOVEMBER 28 TO DECEMBER 11, 1880.

Brown, J. M., Captain and Assistant-Surgeon.—Granted leave of absence for one month, with permission to apply for three months' extension. S. O. 264, Department of the Missouri, December 2, 1880.

Coues, Elliott, Captain and Assistant-Surgeon.—Relieved from duty assigned him in S. O. 134, July 3, 1876, from A. G. O., and to report in person to the Commanding Officer, Department of Arizona, for assignment to duty. S. O. 251, A. G. O., November 26, 1880.

O'Reilly, R. M., Captain and Assistant-Surgeon.—The extension of his leave of absence on account of sickness, granted him August 16, 1880, still further extended six months on Surgeon's certificate of disability. S. O. 259, A. G. O., December 7, 1880.

King, J. H. T., Captain and Assistant-Surgeon.—Granted leave of absence for four months. S. O. 253, A. G. O., November 29, 1880.

De Loffre, A. A., Captain and Assistant-Surgeon.—Relieved from duty at Camp on White River, Col., and assigned to duty at Fort Wallace, Kansas. S. O. 269, Department of the Missouri, December 8, 1880.

Hall, William R., Captain and Assistant-Surgeon.—Assigned to duty at Camp on White River, Col. S. O. 269, c. s., Department of the Missouri.

PHILADELPHIA, JANUARY 1, 1881.

ORIGINAL COMMUNICATIONS.

THE JUDICIOUS USE OF THE MICROSCOPE IN MEDICAL PRACTICE.

Read before the Philadelphia County Medical Society, October 27, 1880,

BY CARL SEILER, M.D.,

Pathologist to the Presbyterian Hospital of Philadelphia.

THERE is no doubt that the microscope is an all-important help to the physician in his practice, if rightly used, and will frequently aid him in solving perplexing questions. But it is argued by most practitioners that it takes too much time to use the microscope, that the eyes suffer from the frequent use of the instrument, and that the work of preparing specimens for examination is too tedious and requires too many accessories. The object of this paper is to meet these objections and to show what can be done in a limited time and with limited means.

In the first place, a good instrument, from a reliable dealer, should be obtained, and should be fitted with a blue glass below the stage, so as to reduce the yellowness of artificial light, which, after all, is more convenient to use than daylight. Two objectives (an eight-tenth or one inch, and a one-quarter or one-fifth, of moderate angle) and two oculars (A and B) usually are included in the price to be paid for the instrument, and are sufficient for all purposes to which the practitioner will apply his instrument. A microtome and a good section-knife should also be purchased; and with these ends the list of apparatus. Of course, more objectives and accessories may be added to the instrument, but they are in most cases unnecessary, except, perhaps, a sub-stage condenser and a bull's-eye lens, which, if properly adjusted, produce an illumination which is not only agreeable to the eye and enhances the definition of the objectives, but also, what is all-important, does not tire the eye in the least; so that the microscope can be used for hours at a time without fatigue to the sense of sight. The fatigue of the eye and the injury to the sight, so often complained of as being caused by microscopical examinations, are in most cases due to the unconscious effort of the eye to see clearly an ill-defined and badly-illuminated object. The best test for illumination is a slide of blood upon which the corpuscles are spread in a thin layer. They will appear, when properly illuminated, as olive-colored disks with a depressed centre and a sharply-defined, intensely black margin; but if not properly illuminated their outline will be misty, and one or more rings will be noticed on the surface of the disks with a bright or dark spot in the centre, according to the focus at which they are viewed. A sub-stage condenser, however, which is not in the centre, so that its optical axis falls in a line with the optical axis of the objective, is worse than none at all; and it should therefore be mounted in such a manner that it can readily be centred, which makes it a rather expensive piece of apparatus. Without it excellent results can be obtained; and most of the discoveries in microscopy have been made with simple instruments handled skilfully.

The preparation of specimens for microscopical examination takes some time and skill, it is true, but not more than even a busy practitioner can afford, provided he is methodical and does not allow material to accumulate. A plan, as I shall describe presently, has been found to work admirably, and three hours a week have been found sufficient to build up one of the richest and best cabinets of pathological preparations in the country.

This plan is as follows. Four wide-mouthed jars holding about one-half pint should be filled three-quarters full of the following solutions: alcohol, forty-five per cent., in No. 1; alcohol, sixty per cent., in No. 2; alcohol, eighty per cent., in No. 3; and alcohol, ninety-five per cent., in No. 4. As the material is collected in the daily route, from operations or post-mortem examinations, each piece, which should not be larger than a cubic inch, is to be labelled, by fastening to it with a pin a piece of stiff writing-paper, upon which the necessary remarks are written with ink, and then to be dropped into jar No. 1. By expending fifteen minutes twice a week in transferring the pieces of material from one jar to the next one, it will be found that at the end of two weeks they will be ready for cutting. If, now, once a week two hours are set aside

for cutting sections, staining, and mounting of all the pieces of material found in jar No. 4, it will be seen that in two and a half hours a week specimens can be prepared, which may be examined during leisure moments.

In order to cut the sections the material is to be imbedded in a mixture of paraffin (two parts) and rendered mutton-tallow (one part), poured while warm into the well of the microtome. When cool and hard, the imbedding material is to be cut away in front and on either side of the specimen, but is left standing behind, when with the section-knife thin sections may be cut. These should then be placed in alcohol, and the thinnest and most complete of them selected for staining and mounting.*

In order to stain the sections they should be immersed for a few minutes in a solution of carmine prepared as follows:

Take of

Carmine, No. 40, gr. xv;
Borax, ℥j;
Water, f℥vss;
Alcohol (95 per cent.), f℥xj.

Mix and filter; then dissolve the crystals remaining on the filter-paper in eight fluidounces of distilled water, and evaporate in a water-bath to four fluidounces. This is called Woodward's Lilac Fluid, and may be purchased from most dealers in microscopical apparatus. From this carmine solution the sections are to be transferred to a solution of hydrochloric acid one part to alcohol (ninety-five per cent.) four parts, in which solution the stained sections should remain a few seconds, until their color has changed from a lilac to a light rose-red, and should then be washed in several changes of alcohol. Finally, they should remain for several minutes in strong alcohol (preferably Squibb's absolute alcohol), and then be immersed in oil of cloves or turpentine in order to make them transparent. After this the sections may be spread out upon a glass slip, covered with a thin cover-glass, and examined under the microscope. If found of sufficient value, they may be permanently mounted in balsam or dammar, labelled, and put away for future reference.

The spreading of the tissue upon the slide, as well as the wiping of the cover-glass, is a rather tedious process, and can be avoided by omitting the clearing of the specimen in oil of cloves, and by using a peculiarly-formed pair of forceps devised by myself some time ago. This may be done in the following manner. After the sections have been stained and have remained in strong alcohol for some time, a clean cover-glass is taken from the bottle with alcohol in which the covers are kept for use. Without wiping it, it is immersed in the alcohol containing the stained sections, being held horizontal by the mounting-forceps, and the section is floated upon it. The cover is then lifted out of the alcohol, with the section lying spread out upon its surface, and a drop of an alcoholic solution of Canada balsam is placed on the section. The cover with the section on it is then put aside, and the balsam is allowed to dry partially, which it will have done in a few hours. When thus partially dried, a drop of crude benzole is placed upon the surface of the balsam, and the cover is placed, with the balsam downward, upon a warm slide, and is gently pressed down.

The time occupied in cutting the section, staining, clearing, and mounting it, will not exceed five or ten minutes if the operator is at all familiar with the different steps; and such familiarity is very readily acquired. I do not want to convey the impression that by this method the best possible preparations of *all* tissues can be obtained, but I claim for it that the preparations will be fairly good, and will answer all purposes for which they are intended.

The examination of fluids, which is so necessary in medical practice, may also be made with little trouble on the part of the practitioner. He should provide himself with a few conical sherry-glasses, and pour the sample of urine or other fluid to be examined into one of them, labelling it with the name of the patient from whom obtained, and covering it with a piece of glass to keep out the dust. After a few hours a small portion of the sediment can be removed with a glass tube, placed upon a slide, and examined. Great care should, however, be exercised in keeping the glasses clean and emptying them immediately after the examination has been concluded.

In order to eliminate one of the most frequent sources of error in microscopical examinations, viz., the introduction of

* For description of the author's microtome, see Proceedings of Philadelphia County Medical Society, vol. i. p. 97, and vol. ii. p. 29.

extraneous matter under the cover-glass, both the glass slides and the covers should be carefully cleaned in the following manner. Place new slides, or such as have been used before, in a mixture of

Potass. bichromate, ℥ij;
Acid sulph. (commercial), f℥v;
Water, f℥xx;

and allow them to remain therein for a day or two; then wash them under a tap and stand them on end upon blotting-paper to dry.

Cover-glasses should also be placed in the above solution contained in a wide-mouthed bottle, and after they have been soaked for some time the acid solution is to be decanted off and clean water is to be poured on and off until all trace of the yellow color due to the bichromate of potassium has disappeared, when the bottle may be filled with strong alcohol, and the covers taken from it and wiped dry as they are needed.

The practitioner will find himself amply repaid for the trouble and time spent upon this work, not only by the pleasure he derives from it, but also by the knowledge he gains, and he will often be better able to understand the symptoms of a given case by bearing in mind the picture which his microscope showed him of the pathological changes in this or that organ.

1346 Spruce Street.

SOLUBLE COMPRESSED PELLETS —A NEW FORM OF REMEDIES FOR HYPODERMIC USE.

Read before the Philadelphia County Medical Society, October 27, 1880,

BY H. AUGUSTUS WILSON, M.D.,

Surgeon in Charge of the Eye and Ear Department of St. Mary's Hospital; Assistant, Medical Clinic, Jefferson College Hospital.

SOLUTIONS for hypodermic use have been very generally abandoned because the *penicillum*, which so soon forms, renders the use of medicines in this form uncertain, if not dangerous.

Because of the danger and uncertainty, as well as the inconvenience of carrying the medicines in solution, the profession has resorted, where practicable, to the use of powders, which are carried either in the hypodermic or pocket case.

It is as a substitute for the latter that I propose the new form of soluble compressed pellets, because of their convenient size and certainty of contents and action. I have confined my experiments to the salts of morphia because it is the drug most frequently used hypodermically, and because I felt confident that if I could succeed with this drug it would be but a simple matter to place in the same form other remedies, such as strychnia, arsenic, apomorphia, etc.

I would here say that Dr. Lawrence Wolff, the well-known pharmacist, has aided me very materially in perfecting the form and in the numerous experiments which have been made.

The result of our first attempt to obtain a soluble pill I now show you. Besides the morphia it contains one-quarter of a grain of white sugar; but the moisture necessary to roll the pills rendered them difficult to dissolve when required. Then the compressed form was tried with sugar; but the smarting, burning pain which immediately ensued led me to believe that the sugar was an irritant to the tissues, and, instead of aiding, really interfered with the process: therefore sodium chloride was substituted, which I found had not the disadvantages of sugar and possessed merits of its own.

The use of the sodium chloride will be apparent when I say that if morphia salts are compressed alone they become extremely hard and very slowly soluble. Hence the necessity of mixing thoroughly, before compression, some material which at the same time shall give increased bulk, be inert, and have a great affinity for water. The sodium chloride acts as a *disintegrator*, for upon coming in contact with water it readily dissolves and leaves the morphia in a fine state of subdivision, ready to be acted upon by water. The sodium chloride, instead of causing pain or irritation, seems really to assist in promoting absorption. To accomplish the solution usually requires not more than thirty seconds, and may be brought about as follows. The syringe is charged with about twenty minims of water, which is poured into a teaspoon or other convenient receptacle; the pellet, being dropped in, is crushed with the end of the syringe, to which the needle fits, and after all the lumps are broken the solution is drawn up and forced out three or four times, when usually the whole mass will be entirely dissolved and ready for use.

I have experimented with nearly all the salts of morphia with reference to their hypodermic use when combined with so-

dium chloride, and would express my belief that the muriate is the one to be chosen. It is the salt that the German practitioners have selected, as being less likely to change when kept for a considerable time; and as the acid is the same as that found in sodium chloride there is no chemical incompatibility. It is slightly less soluble than the sulphate; but this slight difference is counterbalanced by the greater certainty of immunity from change.

It is well known that the addition of atropia sulphate greatly increases the hypnotic and anodyne properties of the morphia salts and decreases the tendency to after-headache and constipation. I have, therefore, used this combination in all my experiments, and would suggest the following formula:

℞ Morphiæ hydrochloratis, gr. $\frac{1}{4}$, .015
Atropiæ sulphatis, gr. $\frac{1}{100}$, .0004
Sodii chloridi, gr. $\frac{1}{4}$, .015
Mix and make into compressed pill No. 1.

I claim that the advantages of this method over any other known are—

1st. The convenient size of the pellets.

2d. That they may be used by the mouth if desirable.

3d. Their certainty of contents and dose.

4th. Their certainty and rapidity of action.

Those who have used the hypodermic method, and have often experienced the disadvantages of solutions and the inconveniences of powders, from their increased bulk and from the difficulty of removing all the powder from the paper, will, I trust, accept this my suggestion, and from actual use decide whether it is or is not an improvement upon existing methods.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

CLINICAL SERVICE OF R. J. LEVIS, M.D.

Reported by Chas. H. Willits, M.D.

RAILROAD CRUSH OF THE LEG TREATED BY AMPUTATION AT THE KNEE-JOINT—INTRA-CAPSULAR FRACTURE OF THE FEMUR—CASES OF FRACTURE OF THE RADIUS, WITH IMPORTANT REMARKS UPON THE PATHOLOGY AND TREATMENT.

GENTLEMEN,—I bring before you this morning a man whose leg has been crushed by the passage over it of the wheel of a railroad-car.

When he was admitted, he was suffering from marked symptoms of shock, which were treated with stimulants and external warmth until good reaction had taken place.

If you examine the leg, you will see that there is great comminution of the tibia and fibula and a good deal of laceration of the soft parts. There is but little warmth in the foot, showing slight vitality, with pulsation present in the anterior tibial artery, but absent in the posterior tibial. Large spiculæ of bone have been removed from the wound, and can be readily picked out now, together with masses of pulpified muscle.

I have consulted with my colleagues, and have decided that, owing to the great destruction of the soft parts, and the cutting off of the nervous and vascular supply to the foot and leg, the only chance the man has for his life is in the loss of the limb. This opinion is also sustained by the experience of this hospital, which bears testimony to the fact that limbs can rarely be saved after having been traversed by the wheels of a railroad-car.

It does not matter what kind of flap I make in this case, whether I cut antero-posteriorly, laterally, from within outwards by transfixion, or shape it from without inwards. The plan usually preferred in this house is the latter one, the objection to transfixion being the superabundant mass of muscle which is contained in the flap. However, whatever form you employ, this rule should always be carried out: to have enough muscle to cover the bone and enough integument to cover the muscle.

As it has been an undecided question in the minds of surgeons which is the safer operation,—through the knee-joint or at the upper part of the leg,—you should be governed in your choice of locality by the condition of the soft parts. In the case before us, that which would offer the best operation is a supra-condyloid amputation at the knee-joint, cutting off the ends of the condyles so as to give a stump free from prominences, suitable for the application of an artificial limb.

I now locate the knee-joint, and, under the carbolic spray, enter my knife a little above the internal condyle, sweep it around to a corresponding point on the opposite side, making a good-sized anterior flap; after dissecting up the flap and removing

from it the patella, I make a short posterior flap, cut the crucial ligaments of the joint, and remove the limb. The ends of the condyles are now to be rounded off with the saw, all sharp edges removed with the bone-forceps, the arteries ligated, and the flaps brought together with sutures. The stump will be dressed with lint soaked in carbolized oil.

I now bring before you a case in which there probably is an intracapsular fracture. It is interesting on account of the obscurity in diagnosis which is always present in these cases, and the bearing which the diagnosis has upon the prognosis.

Intracapsular fracture occurs in advanced life, rarely before sixty years of age, and is due mainly to two causes,—first, to the senile change in the structure of the bone, and, secondly, to the shape of the neck of the femur, which is less obliquely attached to the shaft of the bone than in earlier life.

The present symptoms are alteration in the shape of the hip, pain, very slight crepitus, inability to stand or walk, eversion of the foot, and shortening of the leg amounting to about three-quarters of an inch.

Fractures in this position are produced by the most trivial causes, as a slight slip or twist. In this case the patient says he simply slipped on the ice without falling.

The differential diagnosis between this condition and *extra*capsular fracture is very difficult, and is based upon the following points: the age of the patient; the trivial cause; the moderate amount of shortening,—usually from one-half to one inch; the slight evidences, if any, of crepitus; and the fact that the radius of the arc of rotation in which the trochanter moves is greater in *intra-* than in *extra-*capsular fractures.

Another point which will sometimes clear obscure cases of hip-injuries is based upon the fact that there is normally a limit to the backward movement of the thigh, due to the neck of the bone impinging on the edge of the acetabulum. In these fractures this check is removed: so that if a patient be placed upon his face and the thigh drawn backward it can be demonstrated by abnormal mobility.

In the treatment of intracapsular fractures of the neck of the femur we use the ordinary extension apparatus of adhesive straps and a weight, which is applied for fractures in other portions of the bone.

This is done, not to bring about union, but because it overcomes muscular movements and gives the patient great comfort, and also guards against any dangers from a mistaken diagnosis.

Of course we do not expect union to take place, as the head of the femur is a completely isolated bone floating in synovial fluid, and we have no means by which the fragments could be brought in close apposition.

There is one pathological specimen of a united intracapsular fracture in the museum; but this was doubtless due to the fact that the periosteal connections had not been completely separated.

The prognosis should be guarded, on account of the obscurity in the diagnosis.

The next cases are of a class which I endeavor to show you frequently in this clinic, namely, fracture of the radius.

This is the most common of all fractures, one which is most frequently followed by deformity, and whose pathology and mechanism are least known.

Attention was first called to this subject by Colles, of Dublin; he described a fracture, under the name of Colles's fracture, which he located about one and one-half inches above the lower end of the radius.

Many other prominent surgeons believe the fracture to be about one-half inch from the joint; but my opinion, drawn from some practical studies in the museums here and abroad, leads me to place it one-quarter inch from the lower end of the bone.

Barton, a former surgeon of this hospital, described a fracture of the radius on purely hypothetical grounds, for he had never seen such a case.

His description is as follows: "A chipping off of the posterior edge of the articular end of the bone," allowing the bones of the wrist to slip upwards and backwards.

He thought this would account for the deformity so common in these fractures; but this has never been verified by any cases that I have ever heard of or seen.

This fracture is *transverse*, and is caused by what I call transverse or cross-breaking strain. For example, a patient falls, the hands are thrown out, and the wrist is extended to nearly a right angle. This produces a leverage in a transverse direc-

tion, which is usually sufficient to break the bone.

There is a peculiar deformity, very uniform in these cases, due to the displacement, which is always upwards and backwards, carrying the wrist and hand with it.

The treatment consists in restoring the bone to its former position, and its maintenance there. This is done by extension and forced flexion, and the use of a properly adapted splint.

There are a great many splints devised for this purpose, but they nearly all fail in the very object desired, namely, the retention of the displaced fragments.

Suppose you use a flat splint, as Bond's: your broken fragments are not in a proper position, for you cannot treat a normally *curved* bone with a *flat, straight* splint.

To obviate this, a pad is usually placed in the splint to give it the proper curve, which is then good enough, but is difficult to keep always in position.

In the pistol-shaped splint of Dupuytren, the hand is inverted, thus throwing the convexity of the wrist against the fragments, pushing it still farther out of position. To obviate this difficulty I devised this moulded splint. It is made of copper, can be bent to fit any sized arm, and has a pair of pockets or pouches, into which fit the thenar and hypothenar eminences of the hand, thus effectually preventing displacement.

This splint was made after carefully measuring the normal curvature of the radius and allowing a little for the skin and subcutaneous tissues.

Patients find this exceedingly comfortable; and since I have used it I have had no further difficulty.

PENNSYLVANIA HOSPITAL.

CLINICAL SERVICE OF DR. WILLIAM HUNT.

Reported by HENRY M. WETHERILL, M.D.

RAILROAD CRUSH OF THE LEG TREATED WITHOUT AMPUTATION.

WILLIAM A. FINK, æt. 29, was admitted to the Pennsylvania Hospital, March 22, 1880. About thirty minutes prior to admission the patient was waiting at a railroad-crossing for a train of freight-cars to go by, which had, however, halted upon the crossing. As they stopped he sprang up between the cars and attempted to swing himself across, when the train started, and his left leg was caught and crushed between the bumpers in such a manner as to expose the entire anterior surface of the tibia, the opening being twelve and a half inches in length and four inches in breadth at its widest point. The intermuscular spaces in the soft parts of the leg were torn apart, and the anterior tibial artery was exposed for one and a half inches of its course. Neither tibia nor fibula was broken, and the exposed periosteum upon the tibia appeared uninjured. The entire leg very much bruised, but the main vessels were intact. Shock was not very profound, the patient reacting well in a few hours. Very little bleeding. Leg kept in shape by straps of adhesive plaster, dressed with lint saturated in carbolized oil, and placed in fracture-box. The following is from the ward note-book:

March 26.—Extensive sloughing of integument and bagging of pus in the calf. Strapping removed, all tension taken off, and leg placed in a bran-box with carbolized dressing. Temperature, 104°; pulse, 100; respiration, 22. Quinia gr. viij daily.

April 5.—Temperature, which has been high, shot up to 107.5° after a chill; twenty grains quinia given at one dose. In five hours afterwards, temperature 101°; profuse suppuration and sloughing of muscular tissue and integument. Whiskey fʒiv daily. Urine normal.

8th.—The inner half of the gastrocnemius muscle has sloughed, and was cut away with scissors.

17th.—Midway up the posterior aspect of the thigh is a large collection of pus which has burrowed up along the hamstring tendons. This was evacuated by incision, and a pint of pus escaped. Patient's general condition very unfavorable. Temperature, 103°; pulse, 120, weak.

26th.—After very free suppuration, the opening in the thigh is granulating from the bottom. All sloughing has ceased in the leg, and the large granulating surface looks healthy. No change in treatment. Temperature down to 99°; pulse, 96. Condition improving.

May 8.—Another collection of pus along the hamstring tendons evacuated, this being much smaller than the preceding one.

24th.—Temperature has not been above normal for some days. Stopped quinine and whiskey. Fracture-box is dispensed with, and twenty small grafts of skin from

inner side of arm planted upon surface of ulcer, which has become rather sluggish.

June 4.—These all failed to grow, but have stimulated the ulcer very much.

10th.—Twenty skin-grafts, also taken from his own arm, were planted upon the ulcer, which is closing in under stimulus of grafts.

15th.—These grafts have all died.

25th.—Ulcer not advancing, and granulations getting superabundant. Nitrate of silver applied, and fifteen skin-grafts, taken from another individual, scattered over surface of ulcer.

30th.—Eleven of the grafts have taken.

July 10.—Placed fifteen grafts from a fellow-patient upon ulcer, which is healing very rapidly.

20th.—Last grafts all took. The ulcer, which involved the entire front, sides, and a portion of the back of the leg, being almost girdling, has healed entirely under the use of skin-grafts, and he now walks well without support. Though there is much loss of muscular tissue, yet there is little deformity or loss of function. Although his own skin was repeatedly grafted upon the ulcer, the experiment was not successful in a single instance; but the ulcer was finally closed in by grafts taken from the arms of several other persons.

Discharged cured.

This case is an interesting one, viewed as an example of conservative surgery. Probably few cases ever looked more hopeless; and the excellent result was as little expected by the patient as it was by the attending surgeons.

This man recovered from a temperature of 107.5°,—a circumstance of itself rather remarkable. Did the large dose of quinia abate this several degrees in a few hours? No other means for its reduction were employed.

His temperature ranged between 100° and 104° for a little more than four weeks, during which time suppuration was very profuse, and extensive sloughing of integument and muscles occurred.

Pus-absorption was evinced, at that period when the large collection of pus was evacuated from the thigh, by the slight and almost daily rigors, by the shooting up and down of temperature, by the sallow, dirty color of his general surface, and by the peculiar, sweetish, sickening odor of his breath.

It would have taken unassisted nature very long to heal this enormous ulcer. Skin-grafts, though they may not live, never fail to stimulate a dry, unhealthy ulcer to the formation of laudable pus. It is a significant fact in this case that the patient's own skin-grafts merely stimulated the ulcer, but failed to grow in a single instance, showing the low condition of vitality present; while skin-grafts taken from the arms of healthy individuals grew readily, and soon entirely covered in this almost denuded member,—a circumstance not at all new in the writer's experience, and therefore probably one of which the experience of older surgeons affords numerous examples.

Summing up the features in this case, it might well be called a fair example of tenacity to life under trying circumstances.

1237 Arch Street.

TRANSLATIONS.

Vomiting in Phthisis.—Dr. Ferraud (*Le Concours Médical*, 1880, p. 524; from *L'Union Méd.*), in a lecture on this subject, divides the various kinds of vomiting observed in phthisis into three classes. 1. Mechanical vomiting, resulting from disturbance of the respiratory nerves, and to which a certain amount of gastric or pharyngeal irritation may be added. 2. Gastric vomiting, properly so called. 3. Central or bulbar vomiting. The first variety is that met with at the beginning of the disease. The stomach being full, efforts at coughing give rise to vomiting, and the matters vomited are purely alimentary. This form of vomiting is more apt to occur in the evening. It may be stopped by putting an end to the cough; but this is not so easy a matter. An indication is to prevent the accumulation of glutinous mucus in the pharynx: this may done by means of detersive and alkaline gargles. When ulcers are present in the throat, astringents, tannin, alum, etc., are called for. If these are not sufficient, tincture of iodine or nitrate of silver may be used. Inhalations of belladona or datura are often employed in this form of affection, and M. Woilez recommends that the pharynx be touched with a solution of bromine, one part to six.

Gastric vomiting belongs to the middle period of the disease. The matters vomited are not purely alimentary; they are rather chymous, and transformed by diges-

tion. The cause of this form of vomiting lies in functional trouble of the gastric mucous membrane. Gastric vomiting is of various kinds; it may occur from apepsia, by diminution of the peptic secretion, with increase in the epithelial secretion. It is to be combated by bitters and tonics, and, if necessary, vomitives. In place of vomitives, which we are not often able to prescribe for phthisical patients, calming topical remedies, as chloral, chloroform, ether, may be given, the latter being especially efficacious, as it is peptic as well as calmative. Pepsin and diastase also render good service in these cases. Gastric vomiting from morbid increase in the quantity of secretion is a late symptom. It is best combated by absorbents, as magnesia or charcoal. Astringent powders are still more efficacious in causing absorption of the products of secretion and modifying the secreting surface; rhatany and columbo may be mentioned among these. Powdered opium is also very serviceable in these conditions. Gastric vomiting from spasm of the stomach calls for the administration of narcotics. Opium is first here; then chloral, ether, valerian, chloroform: all may be employed at one time or another. Seltzer water is also useful in this form of vomiting, and atomization of ether against the epigastrium and the back may also be used. Gastric vomiting from special irritation, due either to a deposit of tubercle or to simple irritation, is to be combated by regimen, milk-diet, alkalies, or iodide of potassium in small doses. Plasters of opium, etc., may also be used here. Revulsion may be employed with advantage, in the form of painting with tincture of iodine, vesication, etc. Tincture of iodine may be given in small doses by the stomach, with a view to its modifying action.

Central or bulbar vomiting in phthisis ordinarily occurs at an advanced stage of the disease. It is due to encephalic, especially bulbar, irritation, dependent upon meningeal exudation by neoplastic products. It should be remembered that a vascular change, as bulbar anæmia, like that produced by syncope or migraine or seasickness, may give rise to this form of vomiting. The matters vomited are chiefly mucus and bile. Numerous therapeutic agents may here be brought into play. Chloral is most important, since it will even neutralize the action of apomorphia. Chloroform, which calms the brain and excites the action of the stomach, is doubly useful. Opium and morphia act in the same way, as also bromide of potassium, which may be given in the dose of fifteen to twenty grains at the time of eating. Electricity in various forms has been employed. Nitrite of amyl inhaled to the amount of a few drops has recently proved successful in controlling the cerebral vomiting of phthisis.

Artificial Production of the Signs of Defloration in Young Infants.—At a recent meeting of the Académie de Médecine (*La France Méd.*, 1880, p. 692) Prof. Fournier read a paper on this subject, of which the conclusions were as follows:

1. A sufficient number of cases are on record to authorize the statement that simulation of defloration in young children is at times attempted. The facts are as follows. Artificial production in young children of vulvar lesions, designed to simulate defloration, together with the attribution of these attacks to some individual whom it is in the interest of the accuser to injure.

2. Clinically, these lesions can betray their cause only by some local peculiarity. But this is only accidental, and we do not know of any clinical features by which vulvar inflammation produced by attempts at defloration can be distinguished from one artificially produced for purposes of simulation.

3. The detection of such simulations must depend less on medical symptoms than on the signs of attitude, response, hesitation, contradiction on the part of the child, antecedents of the simulator, various circumstances of the case, etc.

4. It is important for the general safety of the profession and for the dignity of the art to ferret out the ruse and discover the truth. It is not merely right, it is a duty, to confound a criminal accusation and to save the honor, the liberty, and the interests of an innocent person.

5. It is also important, for the same reasons, that the physician should not give a certificate without requisition from due authority. Such a certificate should be confined to the description of the lesions observed, without any estimate of their etiology.

6. Various motives actuate simulators: usually, however, desire of pecuniary gain is the cause.

7. Vulvar inflammations of different kinds usually serve as the basis of imputations of defloration, and these are ordinarily justified to appearance by the allegations of the unconscious or the assertions of the depraved pseudo victim.

Treatment of Pyrosis.—M. Ory (*La France Méd.*, 1880, p. 700) prescribes, in connection with milk and vegetable diet, alkaline drinks. In addition, the following medicinal formula may be employed with advantage:

℞ Pulv. rhei, gr. clx;
Sodii bicarb., gr. xxx;
Syrupi simp., f℥iss;
Aq. menth. pip. ad f℥viij.—M.

Sig.—Tablespoonful twice to four times daily.

M. Ory finds the following powder very useful:

℞ Magnesii calcinat.,
Pulv. sacch. alb., āā ℥j;
Bismuthi subnitrat., ℥j;
Sodii bicarbonat., ℥ss.—M.

Fiat in chart. no. xl.

Sig.—One at the beginning of each meal.

Bouchardat regards the following powder as useful in pyrosis:

℞ Pulv. rhei, ℥iss;
Pulv. opii, gr. ij;
Pulv. magnesii calcinat., ℥iss.—M.

Fiat in chart. no. xv.

Sig.—One before dinner.

Erysipelas.—Tillmanns (*Deutsche Chirurgie; Cbl. f. Chirurgie*, 1880, p. 699), like Virchow, objects to the separation of the deep propagating forms of cellulitis from erysipelas. All forms of cellulitis, even to the acute purulent œdema of Pirogoff, are to be regarded as true erysipelas. In Tillmanns's view, erysipelas originates essentially in the propagation of inflammation, and it is of no essential importance for this view whether the process occurs in the skin or the subcutaneous or subfascial tissues, or spreads through the whole thickness of a limb. Naturally, erysipelas of the mucous membranes and the associated erysipelatous wandering pneumonia are included; while Tillmanns does not accept the primary erysipelas of parenchymatous organs, as described by English authors. Erysipelas is essentially a traumatic, infectious disease. In accordance with the now almost universally accepted view, Tillmanns denies its spontaneous occurrence. Under this head must be taken into consideration the fact that the wounded spot is frequently overlooked or healed, or the erysipelas may first show itself at some distance from the locality of the wound, even in the mucous membranes. In addition, the absorption of the poison through solutions of continuity in the intestinal tract, the lungs, the uterus, as also often in puerperal fever, which is by so many regarded as true erysipelas, must be considered.

The contagiousness of erysipelas, which is so universally received in England and is much disputed in Germany, Tillmanns regards as absolutely proved by both clinical and experimental facts. On the other hand, he expresses himself very cautiously respecting the morphological peculiarities of the erysipelas poison and its relationship to bacteria. At any rate, bacteria cannot be invariably found in every case of erysipelas in the inflamed locality. In spite of staining according to Koch's method, and illumination with Abbé's apparatus, bacteria could not be found by Tillmanns in certain cases, even when bits of tissue were cut from the living patient. In other cases, however, they were found in large quantity. He thinks that there may be bacterial and non-bacterial erysipelas.

In conclusion, Tillmanns passes in review the long catalogue of vaunted remedies. He himself recommends iron, with alcohol as a stimulant and antipyretic. Something may be hoped for from the subcutaneous injection of carbolic acid about the border of the affected part, in the earliest stages of erysipelas. Finally, he alludes to the curative influence of erysipelas in certain tumors, phagedænic ulcers, etc., and suggests its inoculation, *in desperate cases*, from erysipelatous bullæ and blood.

Phlegmonous Periostitis of the Vertebral Column.—An interesting case of this unusual affection was described by M. Poivier at a recent meeting of the Société Anatomique (*Le Progrès Médical*, 1880, p. 869). The patient, a boy of 14, was in the employ of a wine-merchant, and was exposed many times a day to sudden changes of temperature in descending into a damp cellar while in a heated condition. He did not get sufficient sleep, and, in addition, was growing very rapidly. When examined by Dr. Poivier, the patient had a pale, earthy complexion, with an expression of

suffering. He complained of severe pain in the lumbar region, causing him to cry out aloud if touched near this point. His skin was hot; pulse 100. He was constipated. Eight days previously, according to the patient's account, he had been working in the wine-cellar, when he suddenly experienced a sharp, piercing pain in the lumbar region. This gradually grew worse, until at the end of three days the boy had to take to his bed. From this time the fever came on, without chills, however. On examination, which had to be conducted under chloroform, on account of the severe pain which it caused, a swelling could be observed along the vertebral groove about the two last lumbar vertebræ and the sacrum. Deep fluctuation could be felt at one point, and an incision carried down through the periosteum gave exit to an ounce of pus. The vertebra was found bare. A drainage-tube was placed in position, and the patient placed upon nourishing food. His condition, however, became worse; the fever continued, but without chills; retention and incontinence of urine alternated, paraplegia ensued, and the patient sank and died at the end of four weeks from the beginning of the disease. The autopsy showed subperiosteal abscess with purulent infection, but without osseous change,—a true multilocular periostitis of the vertebral column.

Amyloid Degeneration.—Edward Bull (*Nordiskt Med. Arkiv; Cbl. f. Chir.*, 1880, p. 699), in a paper on Bright's disease, endeavors to show that amyloid degeneration is commoner than is generally supposed. He publishes a case of amyloid kidney, in which the time between the operation of the cause of the affection and the first appearance of albuminuria could be proved. This period was thirty hours. The patient, who was 22 years of age, fell ill of a severe phlegmon of the right lumbar region. At once, on November 12, 1878, an extensive abscess was opened, with antiseptic precautions. The urine had been examined regularly for albumen during some time previously, and on the day of the operation, with negative result. On the evening of November 13, however, traces of albumen were found, and this increased regularly in quantity. Death occurred on November 30. Post-mortem examination showed the left kidney pale, swollen, and with amyloid degeneration; the right kidney, which was in the neighborhood of the abscess, was atrophic, but showed no amyloid degeneration, nor did the liver or spleen. Since, then, says Bull, the entry of air to the purulent cavity was necessary to the amyloid degeneration, this cannot have occurred previously to the incision, this view being supported also by the fact that albumen was not in the urine, and also by the limited extent of the process. Bull finds his case pointing very strongly to the rapid development of amyloid degeneration, this agreeing with the fact that the kidneys, as a rule, are attacked by the degeneration at once, or at least very soon.

Organisms in the Viscera in Typhoid Fever.—Prof. C. J. Eberth, of Zurich (*Virchow's Archiv*, Bd. lxxxi. p. 58), has examined the lymphatic glands, spleen, characteristically affected parts of the intestine, and also the liver, kidneys, etc., with a view to discovering the character of the lower organisms said to be pathognomonic of typhoid fever. Of twenty-three cases examined, organisms were found in twelve,—twelve times in the lymphatic glands and six times in the spleen. They were also much more numerous in the lymphatics. Eberth does not regard these organisms as micrococci. They usually assume the rod-shape, and are about the size of the bacillæ found in decomposing blood, only with the difference that they usually take a narrow, oval, or stumpy spindle-shape rather than a cylindrical outline (pictures are given). They are slightly rounded at the end, not cut off sharp. In connection with these rods, small egg-shaped forms are met with, resembling micrococci. Undoubted spherococci were not observed. The peculiar delicate outline of these bodies serves to distinguish them from putrefaction bacillæ. They also contain one to three spore-like bodies, and do not stain so easily in methyl violet as the ordinary micrococci and bacillæ. Eberth gives several interesting facts regarding the comparative number of organisms found at different stages of typhoid, and concludes by asserting the probability that these stand in some relation to the essence of the disease.

Sudden Death from Pulmonary Embolism, after Reduction of a Luxation of the Femur, simulating Death by Chloroform.—A writer in the *Gazette Médicale de Strasburg* (cited by *Le Réveil*

Médical, 1880, p. 202) says we are too apt to place to the account of chloroform every sudden death occurring under narcosis. In a case reported, narcotism was produced by one-sixth grain of morphia and twenty drops of chloroform. The luxation having been reduced in six or seven minutes, the patient, a laborer of 50, suddenly blanched, pulse and respiration failed little by little, and death followed in a few minutes. The autopsy failed to reveal a single one of those symptoms which are usually found after death from chloroform narcosis. On the other hand, the greater branches of the pulmonary artery were almost completely obliterated by quite recent thrombi. The popliteal vein and the veins of the calf, which were decidedly dilated, contained thrombi of the same character. Adipose emboli were found in the finer branches of the pulmonary artery. The causes of death, as stated by the writer of the paper, were displacement of the thrombus of the popliteal vein by reposition and its embolism in the pulmonary artery, together with adipose embolism from injury to the soft parts in the operation. He thinks the surgeon should examine for thrombi, and when these are present must regard the luxation as irreducible.

Paralysis of the Sphincter Ani, following Labor, successfully treated by Means of Interstitial Injections of Ergotin.—Dr. Larger (*Bull. Gén. de Thérap.*, October, 1880, p. 358) had under his care a young woman whom he safely delivered, by means of the forceps, without notable laceration of the perineum. He lost sight of her; but six months later she came to him complaining of an entire incontinence of fæces, dating from her accouchement. The urine was under normal control. On examination, the fourchette was found intact. The anus appeared to be firmly closed, but digital examination showed it easily permeable and giving absolutely no sensation of stricture. It was evidently a case of paralysis of the sphincter, caused by compression from the fœtal head. Dr. Larger prescribed cold rectal and anal douches and one or two suppositories daily, each composed of two scruples of butter of cacao and fifteen grains of Bonjean's ergotin. This treatment failing, interstitial injections into the sphincter ani of a syringeful of ten-per-cent. solution of ergotin were employed. The syringe containing fifteen minims of solution (in laurel-water), 1.6 grains of ergotin were thus injected at once. It was found less painful, later, to inject the amount at three points. Five injections made at intervals of two days sufficed for a perfect cure.

Experimental Researches on the Biological Action of Picrotoxin.—Prof. Chirone and Dr. Testa (*Jour. des Sci. Méd.*, 1880, p. 516; from *Ann. Univers. di Med. e Chir.*) have arrived at the following conclusions. 1. Picrotoxin may give rise to true attacks of epilepsy. 2. Picrotoxinic epilepsy manifests itself independently of the psycho-motor centres: it shows itself in a more intense form, indeed, when these centres have been removed by vivisection. 3. Picrotoxin first exerts its influence on the bulb and on the apparatus of conjunction between the cerebral centres and the spinal centres. In this respect it resembles strychnia and is opposed to cinchonidin. 4. Picrotoxin arouses the functional antagonism which exists between the psycho-motor centres of the bulb and the apparatus of conjunction. 5. Convulsions of the members caused by picrotoxin depend in the first place upon the influence which it exerts upon the bulb and which is propagated by the spinal cord; and, in the second place, upon direct action on the spinal centres. 6. (Omitted.) 7. Epilepsy of cerebral origin may be obtained artificially by cinchonidin, and epilepsy of spinal origin by picrotoxin,—the former occurring provided the psycho-motor centres are not removed, the latter becoming more intense if they have been removed.

Treatment of Acute Articular Rheumatism by Subcutaneous Injections of Ergotin.—Dr. Chevallereau read, at a recent meeting of the Société Clinique de Paris (*La France Méd.*, 1880, p. 724), a communication on the use of ergot in acute articular rheumatism. Having been called to see a little girl suffering with prolapse of the rectum, in whom he desired to use hypodermic injections of ergotin, he found her so crippled with rheumatism that she could hardly be turned on her side to permit the injection to be made. Forty centigrammes of the *solution Yvon* of ergotin having been administered by the hypodermic syringe, next day the rectum continued in position, and, to the doctor's surprise, the rheumatism was much better, and the patient recovered without

further medication. A little later, being called in to see a young lady of twenty-three, who was suffering with severe acute articular rheumatism, confined to the joints of the right side, fifty grammes of the solution were injected, with the result of marked amelioration. The injection being repeated three days later, the patient was completely cured within ten days. This treatment was subsequently employed in a number of other cases, and always with success. The cases were not accompanied by high fever.

Treatment of Virulent Ulcers.—At a recent meeting of the Société de Chirurgie (*Le Progrès Méd.*, 1880, p. 852) Dr. Marc Sée spoke of the resistance which certain virulent ulcers, as chancroids, chancres of the prepuce marked by symptomatic phimosis, chancroid buboes, and phagedænic ulcers, oppose to treatment, months often being required to effect a cure. Dr. Sée operates on these ulcers by scarification with the dermal curette: he scrapes away the pulpy covering of the ulcer, not ceasing until he reaches healthy tissue, and going into every hole and corner. If the case is one of phimosis, symptomatic of chancroid, Dr. Sée frees the prepuce by means of the thermo-cautery and operates as above. But the scraping must be done with the minutest care: the least particle left behind may cause the repullulation of the entire growth. After scraping, the surface thus laid bare is cauterized lightly with the thermo-cautery, after which antiseptic dressings are applied. The operation is painful, and should be done under anæsthetics, but the results are excellent. There is next to no inflammation: at the end of two or three days the ulcer is transformed into a simple wound, which heals with a linear cicatrix in two or three weeks.

A Hitherto Undescribed Nematode found in the Human Peritoneum.—Dr. Victor Babesiu describes, in *Virchow's Archiv* (1880, p. 158), the case of a woman dissected under his direction, in whose gastro-lienal ligament was found encapsuled a worm, fourteen centimetres in length and thirty-five millimetres in thickness, twisted into a spiral. The worm was of even diameter throughout, with pointed head and tail. It was marked by fine cross-lines, with somewhat deeper longitudinal markings. The oral opening was terminal, small, and round; anus almost terminal. Six rather distinct subcutaneous dark-brown oval papillæ. A small, indistinct, excretory opening, probably belonging to some excretory organ, near the mouth. Papillary terminal growths at the point of the short, straight tail; near this a gland. Two thick, twisted, uterine tubes, occupying the greater part of the corporal cavity, with immature, small, oval ova, without shells. A thin vaginal opening just behind the mouth. Dr. Babesiu calls his newly-found treasure *filaria peritonæi hominis*. Pictures of the worm are given.

Giant-Cells in Tubercle.—At a recent meeting of the Société de Biologie (*Le Progrès Médical*, 1880, p. 866) Dr. Cornil communicated a new anatomical discovery relative to the giant-cells which have been studied by histologists during the past seven years. This relates to the impregnation of these cells by particles of carbon or pigmentary matter in the case of old or fibrous tuberculosis. When the tubercular granulations are transformed, we find, on examining them under the microscope, a mass of giant-cells impregnated with pigment. This pigment, which arises from carbonaceous particles or from the coloring-matter of the blood, gives great solidity to the diseased tissue, and, as a result, lengthens the life of the tuberculous patient.

Purgative for Consumptives.—Dr. Ferraud recommends the following prescription in the constipation of phthisis:

℞ Magnesiæ calcinat., ʒss ad ʒj;
Mannæ, ʒj ad ʒij.—M.

To be taken in a cup of tea.

When this is mixed with honey it makes an agreeable electuary:

℞ Mannæ, ʒj;
Magnesiæ calcinat., ʒss;
Mellis, ʒj.—M.

This may be taken in tablespoonful doses in the morning.

Value of Ammoniacal Salts in Diabetes.—Dr. Paul Guttmann (*Bull. Gén. de Thérap.*, 1880, p. 431; from *Berliner Klin. Wochens.*), in a case of diabetes, gave for five days no medication. Quantity of sugar, 231.65 grammes. For thirty-one days administration of ammoniacal salts, 223.11 grammes of sugar daily. Then cessation of treatment for thirty-one days. Amount of sugar, 173.19 grammes per diem; thus showing that, so far from diminishing the amount of sugar in the urine, the salts of ammonia actually increase it.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, JANUARY 1, 1881.

EDITORIAL.

MEDICAL LEGISLATION.

SOME weeks since, in an editorial, we called attention to the need of an efficient medical registration law in this State, and urged the Philadelphia County Medical Society to take the matter in hand. We were not aware at the time that there is a committee of the State Society which is endeavoring to procure the passage of a proper law. We still believe that a committee appointed by the County Society to co-operate with the State Society would, if properly selected, greatly increase the chances of any bill which may be offered at the coming session of the Legislature. The evidence as to the need of the enforcement of such a law needs no discussion, but it is not so indisputable that passage of the bill by the Legislature would be followed by enforcement. It is doubtless true, as asserted by Dr. S. E. Chaillé, of New Orleans, that in 1851 eleven States had such laws, and have since repealed them. The United States contains, however, a very different community from what it did in 1851. A stock argument against reform in medical education was that it had been tried, and failed because it was supported neither by the doctors nor by the laity. Yet the reform has been successful beyond the hopes of the most sanguine of those who struggled for it. It may be that the people are now sufficiently advanced to understand and profit by wisdom which fell years ago upon dull ears. Laws regulating the profession work successfully everywhere else in the world, and as human nature is, in the main, of similar character, the time must come when the proprieties and necessities of the present subject will be recognized. It is certainly still undecided whether that day has arrived; but the drift of the evidence at hand seems to show that the times are ripe.

In Illinois the registry law appears to be exercising a very good influence. In the first year the State Board of Health issued certificates to three thousand seven hundred and eighty-six graduates; to non-graduates based upon affidavits of ten or more years' practice in the State previous to July 1, 1877, and recommendations of reputable physicians, eight hundred and eighty-five; to non-graduates on examination, one hundred and thirty-six: total, four thousand eight hundred and seven. According to the last report of the board, in 1880 there are one thousand less practitioners of all kinds in the State than in 1877; one thousand seven hundred and fifty less unqualified practitioners: also, five hundred and fifty persons, who in 1877 were unqualified to practise, have since, by study in the schools, qualified themselves to practise in accordance with the law. The diplomas of two hundred and ten schools have been recognized, and four hundred fraudulent diplomas from Philadelphia and other cities refused. Certificates have been issued to five hundred and fifty midwives, and three hundred unqualified have ceased to practise.

The work thus accomplished is certainly a good one, and there are evidences that the Illinois Board of Health are intending to do more than they yet have done. We believe it has been judicially decided that the law under which they are acting gives them the sole right to decide which colleges shall be considered to be of such a character that their diplomas shall give the right to practise. We have seen a circular asking for an expression of opinion as to what requirements for graduation by a medical school are the least that the board can recognize. It may be that

some of our Eastern colleges will yet find that Illinois rejects their diplomas.

In Massachusetts, last winter, an attempt was made, by a branch of the American Social Science Association, to get a law passed which required all physicians entering upon the practice of medicine to pass an examination before a State examining board. Petitions were signed very numerously by men of the highest standing in the community having no direct connection with the medical profession, but numerous counter-petitions were also offered, and the proposed law was, after much discussion, rejected. It is plain that the older States are not as yet prepared for a stringent medical-license law; there are too many vested interests opposing, and the general public is not yet sufficiently informed: but the time will come.

We do believe that public opinion has matured sufficiently to render the obtaining of a simple registration act easy, and we believe also that a properly-constructed act would be obeyed. Fines and penalties are good in their way, but a more powerful lever in obtaining obedience would be a clause disallowing claims for medical services by unregistered physicians. If it were known that no professional bill could be collected in court by an unregistered physician, and that executors who paid such bills were personally liable to the heirs and legatees for the amount thus paid, we think the registry lists would soon be filled. Let us not attempt too much this winter, but do let us attempt to get a concise, carefully-drawn registration act. If the attempt be made with wisdom and energy, it must succeed.

CARE FOR INCURABLES.

WE are authorized by Dr. Pepper, chairman of the Finance Committee of the University Hospital, to state that Mr. Henry C. Gibson has offered to erect a new wing for incurables, in connection with the University Hospital, at a cost of about fifty thousand dollars. The plans are being drawn by Mr. Hewitt, the well-known architect, and will be submitted to the examination of a committee of experts in hospital construction, so as to insure the highest degree of perfection in all details. This munificent gift assures the immediate completion of this new department, the need of which has been so urgently felt.

It will have accommodation for about one hundred beds, and will thus afford an incalculable amount of relief to poor sufferers from chronic diseases who cannot afford suitable hospital treatment elsewhere.

The proceeds of the charity ball to be given in behalf of this new department of the University Hospital will now be devoted to its endowment fund, which already amounts to some eighty thousand dollars. Further contributions towards the endowment fund are, however, greatly needed, since it will require the interest on an investment of five hundred thousand dollars to support the entire number of free beds (one hundred) that will be contained in the new building.

This extension was needed because the present accommodations of the University Hospital do not admit of the thorough classification of the cases which will be practicable as soon as the new wing is occupied. It is designed that it shall be ready for patients by October 1, 1881.

It is earnestly to be hoped that the example thus set by Mr. Gibson, of giving during his lifetime a large sum of money to accomplish a definite and greatly-needed object, will soon be followed by others.

All taxes entailed upon charitable bequests are thus avoided, the exact accomplishment of the donor's wish and intentions is secured, and great enterprises are strengthened at most critical moments in the most conclusive manner. We note with pleasure, in this connection, the recent

munificent gift of Mr. Temple to the Academy of Fine Arts, and of Mr. I. W. Williamson to various institutions, and of Mr. John Welsh in founding the professorship in the University, which bears his honored name; but there is still ample opportunity and most urgent need for similar large gifts, especially to this latter institution (the University of Pennsylvania), to supply the advantages which are imperatively necessary for its proper expansion and full prosperity.

A library-building of spacious proportions, to contain the large collection of the University, is greatly needed; but even more importunate is the need for the endowment of professorships and scholarships, which would encourage science and learning and relieve the financial needs of this great educational institution.

DEATH DURING ETHERIZATION.

IN the *Cincinnati Lancet* of October 30 there is a long account of a death which recently took place during the administration of ether in that city, and in the *Boston Medical and Surgical Journal* for December 2 is an editorial discussion of the subject. It seems to us that our New England contemporary is correct in believing that the best chance was not given to the patient. The woman was exceedingly feeble, had been operated upon twice before, and, according to some statements, had septicæmia. When it was first noticed that anything was wrong, both respiratory movements and pulse had ceased. Surely there must have been some warning which a trained expectant eye might have noticed before things came to this pass. An irregular respiration, a pallid face, or a failing pulse ought to have given notice of the danger.

Then the means adopted for resuscitation are not above criticism. Artificial respiration was not maintained as steadily and persistently as one would expect; and the amount of stimulants given was simply extraordinary. One and a half pints of brandy were administered hypodermically and by the rectum during the two and one-half hours which the woman lived after the removal of the anæsthetic.

It must be recollected that the patient was dying largely, if not altogether, through narcotism of the respiratory centres. Alcohol is not a stimulant to these centres, but a paralyzant; and it was given to a narcotized woman in an amount sufficient to endanger fatal narcotism in a healthy woman. Ether and alcohol act almost exactly alike upon the nervous system; and to give alcohol in such a case is almost the same as giving more ether. The correct treatment is to be found in the hypodermic use of atropia as a respiratory stimulant, and, if a cardiac stimulant is also needed, the injection into a vein or under the skin of solution of ammonia and tincture of digitalis.

Of course, it is easy to criticise from a distance, and the position here taken may not to others seem correct; but we are not willing that the case under consideration should render the profession afraid of ether as an anæsthetic without its being clearly pointed out that it is far from certain that ether, and not alcohol, was the final cause of the death.

HOSPITAL STEWARDS, U.S.A.

SOME year or two since, we called attention to the present status of hospital stewards in the United States Army, with their unjustly low rank and compensation. Congress has hitherto afforded no relief to the just complaints of those of whom so much is required and to whom so little is given.

We trust that success will crown the efforts now being made for higher recognition of services. We see no reason why, if under the name of apothecary a man in the navy receives sixty dollars a

month, his compeer in the army for exactly similar services should be paid thirty dollars.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting of the Society was held at the hall of the College of Physicians, Philadelphia, October 27, 1880, Dr. Albert H. Smith, President of the Society, in the chair, at which Dr. Carl Seiler read a paper on the "Judicious Use of the Microscope in Medical Practice" (see page 193), and exhibited a mechanical microtome and several microscopic specimens. On motion, the thanks of the Society were tendered to Dr. Seiler for his paper.

Dr. E. O. Shakespeare said that he had been much interested in the paper, and thought that it discussed a matter of great importance to the student of medicine of the present day, and very practically useful to the busy practitioner, especially since the lecturer has shown that the preparations can be made in a very short space of time and in a very satisfactory manner. He felt that from his own experience he could endorse everything that had been said in the paper.

He wished to say a word in favor of the machine just exhibited to the Society for cutting sections, which he regarded as perhaps the best one of the kind ever devised for those who have not much experience in making sections with the knife, and also for making large sections of the brain and other organs, where large areas must be observed in order to trace the morbid process. He had seen beginners in microscopy make sections with this machine that were sufficiently thin for examination by high powers of the microscope.

Dr. Seiler said that all that he had intended to demonstrate was the feasibility of making sections and the use of the microscope by the busy practitioner. The cabinet which he mentioned was made by Professor Christopher Johnson, a busy practitioner of Baltimore, who has the best collection of any in the country, except Woodward's at Washington. Dr. Johnson follows the plan laid down in the paper exactly, and thinks that this method is the best one. It may seem expensive, on account of the alcohol, but really little is wasted. It is only necessary every two or three weeks to throw out the weakest solution and, degrading the rest, fill up No. 1 with ninety-five per cent. alcohol.

In concluding, the lecturer stated as an important point that the object in making microscopical preparations would not be attained unless the practitioner knew what he saw and what to look for. This requires hard study; and he was very glad to say that the different medical colleges all over the country are now introducing obligatory courses on histology and morbid anatomy. The student will therefore be in the future better able to carry on microscopical examinations with such practical hints as are to be found in the paper of the evening, and thus continue his microscopical work in conjunction with his daily practice.

Dr. H. A. Wilson read a paper on "A New Form of Remedies for Hypodermic Use" (see page 195).

Dr. M. O'Hara approved the suggestion, as he had heard it stated that powders of morphia lose their power after being carried for some time.

Dr. A. L. A. Toboldt suggested tartaric acid as an excipient, instead of sodium chloride, as it renders alkaloids more soluble.

Dr. Charles H. Thomas had been carrying morphia powders for many years, and never had any difficulty in keeping them, nor any evidence of failure. The method of Dr. Wilson, however, is an admirable one. The sodium chloride is not objectionable, as its solution is even less irritating to the tissues than pure water. This form has a marked advantage over the powders in point of solubility, especially if they have been kept for any length of time.

Dr. W. R. D. Blackwood had been in the habit of using morphia powders for hypodermic use for the last fifteen years, and was satisfied that morphia does not deteriorate at all. Moreover, in getting powders from a druggist, it is impossible to tell how long he has had the morphia on hand before dispensing it. In a case of intestinal colic he had made this experiment purposely, and could detect no difference whatever between fresh morphia and the old powders. His method is to carry morphia in one-quarter grain powders, which may be divided or increased as requisite. The syringe is filled with water, which is then ejected into a spoon, the powder dissolved and drawn again into the syringe and deposited beneath the skin. In this way the solution is definite in strength. No more is made than is necessary at the time, and penicillum is avoided. Other agents may be used in the same way. The pellets exhibited will doubtless fulfil a good purpose. During the last few years gelatin disks have appeared, which are valuable for their portability and accuracy in measuring the dose in hypodermic and ophthalmic medication.

Dr. John B. Roberts saw a special advantage in these pellets in hospital practice, where nurses who may be careless have to administer the remedy. The hypodermic syringes are often incorrectly graduated. If solutions are preferred, however, there should be no difficulty in preventing the fungous growth by adding tartaric acid to them; but the

present form has especial advantages in its convenience, easy solubility, and accuracy of dose.

Dr. John H. Packard said that for years he had been using powders of the pure alkaloid, instead of the sulphate of morphia. He never had any difficulty in dissolving them. He obtained them in quantities of fifty (half-grain papers), but never noticed any deterioration or change, even after keeping them for years. He was satisfied that there is much inaccuracy in graduating syringes. He preferred the powders, using hot water, and taking the whole, a half, or any part of one of the papers, according to the amount he desired to give, discharging the water upon the powder, and then drawing it up, performing this several times. He has had no difficulty in obtaining a clear solution. He does not, however, use the hypodermic syringe as frequently at present as he formerly did, on account of the strong objections raised against it by persons whose opinion he respects. The disagreeable effects of morphia can generally be overcome by taking a cup of strong coffee.

Dr. Charles B. Nancrede spoke of a case that was very much affected by opium, where the headache and general distress were relieved by half a drachm of the fluid extract of ergot.

Dr. H. A. Wilson, in closing the debate, said that he would like these hypodermic pellets to be submitted to actual trial by the profession, in order to determine whether they are of any real value. He had experimented with different excipients upon his own person, and had found sugar and other substances are slightly irritating, but table-salt is not. The pills are accurately weighed and lightly compressed by Mr. Wolff, who had agreed to furnish them at a cost not greater than that of the powders.

For keeping several varieties in the hypodermic pocket-case, he recommended short tubes with a diaphragm in their middle and containing a different kind in each end.

On motion, a vote of thanks was tendered to Dr. Wilson for his interesting communication.

SANGUIS BOVINIS EXSICCATUS.

Dr. William H. Pancoast presented a specimen of a new form of condensed nourishment, consisting of dried bullock's-blood, prepared at the Jersey City stock-yards, under the supervision of Dr. F. E. Stewart, for Messrs. Parke, Davis & Co. This substance is given in place of beef-tea, and similar articles for the sick, mixed simply with water (℥j to ℨj), or, better, with brandy and glycerin. It may be given in nutrient enemata as well as by the mouth.

Dr. Stewart, being present, was, on motion, invited to explain the process of preparing the blood. He said that dried blood had been used extensively in New York, and was now under trial at the Blockley Hospital, Philadelphia. The process of preparing the blood is very simple. The fresh blood is obtained by bleeding the animal to death, the fibrin is rapidly removed, and the rest of the blood is exposed in shallow vessels to a temperature not above 110° to prevent coagulation of the albumen and its devitalization by excessive heat. The dried blood is afterwards coarsely broken up and packed in air-tight cans. It is important that the animals should be bled to death, for if they die of apnœa the product will be less fit for medical purposes. He commended particularly the form of administration in an elixir (℥ij in ℨvj).

The thanks of the Society were tendered to Dr. Stewart for his explanation. F. W.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, NOVEMBER 11, 1880.

THE VICE-PRESIDENT, Dr. JAMES TYSON, in the chair.

Cancer of the lower portion of the œsophagus and the stomach. Presented by Dr. E. T. BRUEN.

THE specimen affords an example of cancer of the œsophagus at its termination in the stomach, and the growth has involved the tissue of the cardiac end of the stomach, along its greater curvature more especially. The mucous membrane of the stomach is still intact, although it bulges inward from the presence of the growth, the masses of which can be felt as large as though two or three walnuts were encased beneath its folds. The spleen is found tightly bound to the stomach, the left lobe of the liver as well, and the lung was also fixed. This is shown by the fragments here exhibited. Almost the natural lumen of the œsophagus is preserved. I could introduce my finger with ease before I opened the tube. This I had inferred before death, because I could introduce a fair-sized bougie into the stomach, and this was several times accomplished during life.

All the other tissues of the body were found at the autopsy to be normal. The interesting clinical facts connected with this case can be briefly stated as follows:

1st. There was no evidence of previous cancer in the family history of the patient.

2d. Although dyspepsia and failing strength had been noticed for six months before the case came under my care, yet all this time the patient was not prevented from attending to her occupation as washerwoman, and she did not apply for treatment till about six weeks before her death, when obstinate, uncontrollable vomiting rendered her unable to work, and she entered the hospital. The material vomited never contained blood, and we now recognize that there is no ulceration of the mucous membrane of the stomach.

3d. The only dulness was furnished in the normal splenic area, and the tumor was situated so high in the left hypochondrium that palpation was equally futile: so no assistance was furnished by physical examination.

4th. Much flesh was lost during the six weeks of vomiting; but little had been lost before, although the patient admitted that she was conscious of failing strength for the six months previous to admission to the house.

5th. The age of the patient was 58 years.

6th. There was some albumen in the urine, and its specific gravity was low (1009), and the question, "Can the vomiting be symptomatic of deficient renal activity due to cirrhotic changes?" was entertained. The hypothesis was, however, not supported by any hypertrophy of the heart or evidence of increased vascular tension.

7th. In forming a diagnosis in the absence of positive symptoms, I could only infer that cancer existed.

8th. The adhesions presented by this specimen are of interest in studying cases of cancer of the stomach. I have now a case in my wards in which adhesions have apparently been formed between the pyloric end of the stomach and the under surface of the liver. Thus a possibility of cancer of the left lobe of the liver is simulated. In such a case the pylorus, weighted by the growth, is sometimes quite movable, and can thus be distinguished from a cancer of the liver, and yet sometimes the adhesions may prevent much movement: so in such a case it can cause pressure on the aorta, and murmur which is influenced by position.

I should like to pursue this subject, but believe that this is not in conformity with the scope of this Society.

Dr. TYSON said that the case was interesting to him chiefly from the fact that the carcinomatous growth projected outwards, instead of encroaching upon the lumen of the stomach, as is usually the case.

Dr. HENRY remarked that the case just reported opened up a very nice question in diagnosis. It will be recalled that the urine was of low specific gravity—1009—and contained albumen, but its diurnal amount was not mentioned. This abnormal condition of the urine coexisting with obstinate vomiting, it was natural, in the absence of *signs* of gastric disease, to attribute the condition of the patient to a diseased state of the kidneys; but Dr. Bruen was led, chiefly, he believed, from the extremely obstinate character of the vomiting, to suspect, and, as Dr. Henry understood him, to diagnosticate, a carcinoma of the cardiac end of the stomach. Bright's disease had been excluded on account of the absence of cardiac hypertrophy and increased vascular tension. Cardiac hypertrophy, although the rule in cases of contracted kidney, is by no means invariably met with. For its development a good state of nutrition is essential. This fact was illustrated by a specimen of extreme cirrhotic atrophy of the kidney, associated with phthisis, recently presented by Dr. Henry to the Society. There was no cardiac hypertrophy, the low state of the patient's nutrition forbidding this compensatory action on the part of nature. On the contrary, the heart was somewhat below the average normal size, of flabby consistence, and somewhat fatty. Dr. Henry did not recollect whether Dr. Bruen had made any particular mention of the post-mortem appearances of the heart and kidneys in the case just reported.

In reply to Dr. Henry, Dr. BRUEN said that the statement that the other tissues and organs were normal had been overlooked: this of course included the condition of the cardiac muscle. Dr. Bruen did not think Dr. Henry's case of phthisis with granular kidney, yet without cardiac hypertrophy, a parallel case with that under discussion. In his case the general nutrition had been good up to within a few weeks of the death of the patient, while Dr. Henry's was a case of chronic wasting disease.

Hypertrophy of the heart with accentuation of the sounds, especially the second, is recognized by Dickinson and others as most frequently associated with renal fibrosis. In his clinical experience these facts were cardinal points of diagnosis. If, as occasionally happens, the patient suffers from wasting disease, these conditions may not be present, but even the dilatation of the heart is probable. He considered his point well taken,—viz., that the absence of accentuated sounds and cardiac hypertrophy excluded renal alteration, for the wasting had been rapid, not chronic.

Cancerous tumor of the mediastinal glands and of the lung. Presented by Dr. EDWARD T. BRUEN.

I cannot present this specimen with the clinical study which its importance demands, because the patient died the day after I resumed charge of my wards in Blockley, and was almost moribund when I saw him. The immediate cause of death seemed to be dyspnœa from the presence of a large right-sided pleural effusion. Tapping of the chest was accomplished, and three pints of liquid were withdrawn, but the patient died a few hours afterwards.

Post-mortem.—The body was fairly nourished. Rigor mortis marked. On removing the sternum, the large mass now exhibited was found filling the entire mediastinum and involving the cervical glands. The cervical glands presented a mass as large as a small bunch of grapes, reaching up some distance above the clavicles on both sides. No glandular enlargements were noted elsewhere. The costal pleura was healthy, but many nodules were scattered through the right lung and pulmonary pleura. Elsewhere all the tissues and organs were notably normal. I think during

life the dulness over the mediastinum, contrasted with the flatness over the effusion, and the presence of the enlarged glands in the neck, would have been helpful aids to establish the diagnosis. One of the earliest symptoms in these cases has been pain, sometimes localized, sometimes radiating down the chest or down the arms. This is a really fundamental symptom, and is useful before percussion can be employed. The difficulty confronted in some cases is to distinguish this pain from that caused by commencing aneurism before the aneurism is attested by a murmur. This suggestion applies especially to that form of aneurism known as dilatation of the aorta. The effusion must have taken place in consequence of inflammation of the pleura, since many shreds of lymph were found floating in the fluid; but the pressure from these enlarged glands might have produced the same effect. I have under observation a case of adenia, or enlargement of the bronchial and cervical glands, without evidence of corpuscular blood-change or scrofula or syphilis, occurring in a young man about thirty years of age. In this case, although the interference with the intrathoracic circulation has caused a general enlargement of the superficial veins of the body, there is no pleural effusion. I think that the pleural effusions in cases of mediastinal cancer mean oftenest a secondary cancer of the pleuræ. A microscopic examination of this growth showed its structure to be that of a carcinoma of the medullary variety. A section prepared by Dr. Formad is ready for your inspection.

Aneurism of the innominate artery. Presented by Dr. J. H. MUSSER.

As Medical Registrar at the Hospital of the University, I had the opportunity of observing the patient from whom the specimens were taken, and through the courtesy of Prof. Pepper I am allowed to present them to you.

Admitted to the hospital August 1, 1880, the patient was 34 years of age, a native of Wales, and a resident of Dauphin county, Pennsylvania. For twelve years past his occupation has been that of a miner, working hard and exposed to all its hardships. A constantly moderate drinker, at times he would spree. Always used tobacco moderately. Eleven years ago had a sore on the penis, said to be a chancre. A year afterwards he had subacute rheumatism, lasting a year. No other symptoms of syphilis. Save an attack of pneumonia, he has been perfectly healthy. Family history, so far as can be ascertained, good.

While working in the mines when they were on fire, in January, 1879, he caught cold, and thenceforth suffered from shortness of breath, stiffness in the neck, and a "twitching" sensation in the larynx; the latter symptom occurring at intervals, the others being constant, though variable in degree. In January, 1880, he applied to a physician for treatment. At that time he was said to have bronchitis and chronic laryngitis. Early in July he had an attack of what was said to be œdema of the larynx. A few days afterwards a "lump" broke in the throat, with the discharge of purulent matter. Since then he has expectorated blood. After the breaking of the "lump" the dyspnœa was relieved. During the year he has lost flesh and strength. His appetite has been poor, and he has had night-sweats. At present he is a moderately stout man, with a large frame, weighing one hundred and sixty-two pounds, face slightly flushed, not anæmic, skin warm and moist, fingers not clubbed, dark eyes, large eyelashes, hair in abundance, dark, teeth good, natural countenance, tongue coated and flabby, pharynx slightly congested, no blood on it or point of hemorrhage, tonsils and half-arches normal, no dyspeptic symptoms, bowels regular.

Laryngoscopic examination by Dr. McCracken, in charge of throat department, revealed only slight infiltration of the tissues about the glottis, absence of paralysis of either vocal cord, in the trachea at the right a mass of blood. Did not notice any occlusion of the tube. At the larynx there is a hoarse, coarse inspiratory sound; the sound is transmitted all over the thorax, so that it is almost impossible to hear the respiratory murmur. The percussion-note at the left apex was a little higher-pitched than normal. Expansion of the apex and of the whole lung was poor. Constant cough; continuous expectoration of bright arterial blood. Pulse 70, heart normal, special senses and mental faculties unimpaired.

Further note.—For three days the hemorrhage continued; on the third day death resulted from a sudden enormous hemorrhage.

Post-mortem.—All the tissues and organs, except the lungs, exsanguious. The organs were healthy. The lungs, air-cells, bronchials, and bronchii filled with arterial blood. On opening the thorax, the heart and lungs were in their normal positions. The inner sides of sternum and ribs were not pressed upon. The innominate veins were normal in position and size. The trachea was not noticeably deflected. The ascending and transverse portions of the aorta were dilated, the upper part being more expanded. The innominate artery was dilated, the dilated mouth being continuous with the dilated aorta. The expansion of the innominate was not uniform; anteriorly there were one or two sacs, posteriorly a large sac pressed against, became united to and ulcerated into the trachea. The right carotid arose from the common expansion of the aorta and innominate, the subclavian one and a half inches from the carotid, above and at the right of the mass. The dilated portions of the aorta were atheromatous. Within the aneurism, completely filling it, was a large, moderately firm, pale-red clot;

left ventricle of heart slightly hypertrophied; valves normal. I should have mentioned that the pneumogastric nerve was seemingly much pressed upon, as the cords of the plexus were quite flattened where they passed over the mass. The recurrent laryngeal was not pressed on.

The diagnosis was not made before death. It was thought to be incipient phthisis with tumor. I thought there must be something causing pressure. I had no opportunity for a second examination. Had more careful percussion been performed, the dilated aorta and the aneurism could probably have been defined. Comparison of the radial pulses might have given a clue. There was no projection, no pulsation, neither thrill nor murmur, nor were there any external evidences of pressure within.

The continuous dyspnœa, persistent stiffness of the neck at the root, with soreness, and the "twitching" sensation, are worthy of note. The July attack was due to œdema probably, and the "breaking of the lump" to the completion of the ulceration, hemorrhage being prevented by the protruding clot.

I am positive that the circulation of the right arm was not interfered with nor the pulse much altered, as it was at that arm I noted the pulse.

Dr. BRUEN had for some time past in the study of aneurism taken as fundamental evidence for its diagnosis two series of facts,—viz., 1st, the sequence of disease of the arterial coats upon some prior cause capable of producing inflammation of the arterial coats; 2d, symptoms of pressure. The pressure-symptoms seem to have been overlooked in this case. It was indeed true that other diseases besides aneurism might give similar pressure-symptoms; but as a rule they could be differentiated easily. He knew of a case in which an erroneous diagnosis of dilated aorta had been made, when fifteen months afterwards mediastinal cancer was undoubted; cases of this sort are exceptional.

Auscultation and palpation were not as important, in his estimation, as the above points, for a deposition of laminated clot might prevent murmur, thrill, or pulsation. In proof of this, he would recall to the remembrance of the Society a case reported by him to this Society about one year ago,* in which case multiple aneurisms had been found after death, completely filled with laminated clot, so that no blood could enter them. During life, murmurs could be elicited only by pressing the most superficial tumors upon the aorta, thus obstructing its lumen. In these cases the pressure-symptoms, aided by percussion, were most interesting.

Two cases of abdominal tumor which he had lately seen presented the same symptoms as regards murmur and palpation signs of tumor. In one there was a specific history, and a peculiar pain relieved by a position of the body prone upon the face. In the other there is no history of syphilis, alcoholism, or renal disease, nor is there the significant pain relieved by change of posture.

In one of these cases the diagnosis was verified by autopsy, revealing rupture of an aneurismal sac; the other, Dr. Bruen believed, will be demonstrated at an autopsy to be carcinoma, probably of the stomach, and the diagnosis was made by attention to his cardinal points. In abdominal carcinoma adhesions might form, which might so fix the tumor as to cause a murmur not affected by change of position.

Dr. MUSSER, in reply to Dr. Bruen, called attention to the fact that he had stated in his notes that perhaps more careful percussion would have detected the tumor and the dilated vessel. Neither, however, encroached upon the lung, as that organ was most carefully examined. The anterior view of the tumor was small, dilatation of the aorta not very great, so that the area of dulness would certainly have been small. Pressure-symptoms were noted, but the sudden death of the patient prevented the cause from being investigated fully. The stridulous respiration, its seat loudest in the larynx, the paroxysmal attacks of dyspnœa, finally growing constant, were due, probably, to the stricture of the trachea.† Œdema of the glottis might have been produced by obstruction to the venous return from pressure. The flattened condition of the right pneumogastric nerve should have caused some more constant symptoms. The paroxysms of dyspnœa might have been thus produced.

Dr. BRUEN asked if the dyspnœa was spasmodic or constant.

Dr. MUSSER replied that at first it was spasmodic, but latterly it was very slight, but constant.

Dr. BRUEN referred to a case of spasmodic dyspnœa resembling asthma, which was due to aneurism. He had already this evening referred to this case. The aneurismal growth had compressed the pneumogastrics and trachea, and produced the same whistling respiration noted in Dr. Musser's case, and horrible asthmatic seizures, although there was always some dyspnœa. In Dr. Musser's case these symptoms would probably have become more marked as the tumor enlarged.

Dr. B. also wished the Society to note that he had also read before them a paper (afterwards published in the *Medical Times* of May last) on mitral obstruction, in which he had claimed that murmurs indicative of mitral obstruction were heard with maximum intensity over the auricle, following the or-

* Meeting of October 23, 1879; also Medical Times for October 11 and 25, 1879.

† Ziemssen's Cyc., art. Occlusion of Trachea.

dinary law, that murmurs are heard with maximum intensity at that point where the cavity in which they are produced approaches closest the surface of the chest. This, with accentuation of the second sound at the pulmonary artery and enlargement of the auricle, often helps to disentangle a confused murmur.

Dr. MUSSER thought these symptoms were due to the pressure on the trachea, especially as the same dyspnœa, early in July, was relieved by the "breaking of the lump," which had doubtless lessened the tension of the aneurismal sac. He would also call attention to the constant soreness and stiffness at the root of the neck.

Dr. TYSON asked if any disease of the lungs had been detected post mortem.

Dr. MUSSER replied that none had been observed.

Epithelioma of the foot. Exhibited by Dr. H. F. FORMAD.

This specimen is taken from the dorsum of a foot removed by Professor Agnew last winter in the University Hospital surgical clinic. The following history was obtained through the kindness of J. W. Worrell, student of medicine at the University:

The patient, a robust young man of 27 years, acquired fourteen years ago a compound fracture of the os calcis, the foot being caught between the wheels of a threshing-machine. The patient recovered from the injury with a stiff ankle-joint, but at the end of six months the cicatrix began to slough, in which condition it remained for six and a half years; then it again healed up entirely. The cicatrix, which had a very scaly appearance, remained, however, closed but one month; then it opened by one single long fissure or break, and has remained an open superficial ulcer ever since. For five years the edges of the ulcer remained smooth, then they became rough. The ulcer used to increase very slowly in size, more rapidly during the last six months. There has always been a very offensive discharge; it has always been painful and itching; never bleeding of itself, but bleeding readily on the slightest injury. At the time when the patient came to the University Hospital clinic the ulcer was covering an area of twenty square inches, in its longer diameter reaching around the dorsum of the foot, from the external to the internal malleolus. The diagnosis was, as in all such cases, that of indolent ulcer.

Microscopic examination of sections taken from all parts of the ulcer revealed it to be a typical squamous epithelioma crowded with characteristic pearly bodies.

Dr. J. H. PACKARD agreed with Dr. Formad in thinking that certain indolent ulcers were in reality epitheliomatous, and instanced a case in point.

Dr. FORMAD said that he should like to call attention to the youth of the patient from whom this specimen had been removed, for the books generally state the contrary. In his experience he had had several opportunities of examining similar ulcer-like epitheliomata removed from comparatively young subjects.

Dr. NANCREDE said that some five years ago he had presented to the Society for Dr. J. Ashhurst, Jr., a specimen of pigmented papilloma of the groin, which showed the commencing invasion of the subcutaneous tissue by epithelial elements. The patient from whom it was removed was about 18 years of age, and she had remained perfectly free from the disease up to the present time, he believed, owing to the early and free removal of the growth. He also cited a case of so-called "Marjolin's ulcer," giving a detailed account of the microscopical appearances.

Dr. TYSON agreed with the views propounded by Dr. Nancrede, and said that the evident inference to be drawn from the facts related this evening was that early and radical surgical intervention should be resorted to in such cases.

Dr. BRUEN said that he knew of numerous cases of ulcers which had proved intractable for many years,—perhaps twenty,—and which yet showed no evidence of epitheliomatous change.

Dr. FORMAD could not admit that the base of an ulcer, consisting as it does of mere granulation tissue, could become epitheliomatous. The indurated margins of the ulcer, containing epithelial elements, could, however, readily undergo this change.

Dr. TYSON said that Dr. Formad's remarks really opened up the much-vexed question of epithelial new formations. Where a new islet of cicatrization appears in the centre of a sore, the same difficulty arises as to the explanation of its genesis.

Dr. PACKARD said that his remarks had reference to mistakes in diagnosis.

Dr. SHAKESPEARE remarked that he had lately been asked to examine a fragment removed from an obstinate chronic fungous ulcer on an old woman's leg, who had been for many years an inmate of Blockley. Under the microscope, sections of this showed plainly its epitheliomatous nature.

Mitral, aortic, and tricuspid valvular disease; red atrophy of the liver; cirrhosis of the kidneys and pancreas. Presented by Dr. J. H. MUSSER.

The specimens I present are from a patient who died in the University Hospital. The history is as follows:

Maggie M., white, æt. 26, single; born in Dublin; but three weeks in this country; domestic. Father and mother living; six brothers and sisters dead, cause not known by patient. No cancer or phthisis in the family to the patient's knowledge. Five years ago had acute rheumatism; no other illness.

September 22 of this year she was suddenly

seized with vomiting and slight fever. In two days the vomiting was replaced by pain in the xiphoid cartilage. On the 27th she became jaundiced. The above is the patient's story of her condition previous to admission. I may say she drank daily of ale and porter, occasionally to excess.

October 2, her condition was as follows: emaciated and anæmic; skin and conjunctivæ jaundiced. Face dusky, lips blue, countenance anxious; hands and feet blue and cold, fingers clubbed; temperature 95°; mind dull. Tongue dry, heavily coated with a dark fur; thirst; no vomiting; loss of appetite; pain and tenderness upon pressure on epigastrium. Liver dulness in mammary line begins at fifth rib and extends to the margin of the ribs. In median line, dulness extends to two inches below xiphoid cartilage. Slight diarrhœa, stools light yellow. Breathing hurried; lungs healthy; cardiac impulse in second, third, and fourth interspaces, one, one and a half, and two inches, respectively, inside the nipple-line, and in the fifth interspace one-half inch outside nipple. Palpation shows same as inspection, and in addition an epigastric impulse is noted, and at the apex a slight thrill. Cardiac dulness begins at second interspace above. The right border corresponds with the right edge of the sternum, the left with the left limit of the impulse-area. Heart-sounds extremely tumultuous and difficult to define. The first was somewhat booming, with a murmur over the mitral area. At the aortic cartilage a feeble systolic sound, possibly transmitted; pulse very small, weak, irregular, about 160. Urine: reaction, acid; specific gravity, 1021; albumen present; sugar absent; sediment, few granular and numerous hyaline casts, some of them containing red blood-corpuscles; fatty epithelial cells from the bladder and urethra, some of them stained yellow; few pus-cells; irregular granular masses of brown pigment and broken-down red blood-cells.

October 3 and 4, condition about the same. Later, the night of the 4th, she had an attack of dyspnœa, and of severe pain over the sternum and in the right side. There was dulness at the base of the right lung, and subcrepitant râles. Digitalis and carb. ammonia, with dry cups, gave some relief. At 4 A.M. she almost went into collapse; her extremities were cold and blue, face dusky; pulse imperceptible at wrist; heart very rapid, weak, and irregular; subcrepitant râles and dulness at the base of left lung, also. Internal and external stimulation caused relief, so that in the morning she had only slight pain and oppressed breathing; extremities were warmer, face more natural, although jaundice seemed increased; pulse was 150, stronger and more regular. Congestion of lungs posteriorly continued; slight diarrhœa, pale stools; no vomiting.

October 5, 4 A.M., another attack of dyspnœa. At the morning visit the pulse was improved slightly, as was also the dyspnœa; jaundice slightly increased. In the afternoon she became dull, not answering questions readily; heart as usual; no dyspnœa; urine not passed so abundantly as in health.

October 6, weak; breathing hurried; effusion in both pleuræ; heart's action very rapid and feeble, irregular; pulse not felt. Death at 10 A.M.

Dr. FORMAD made the following report of the post-mortem, made by Dr. Hughes, three and a half hours after death:

External appearance: whole body jaundiced; large yellow patches about the head, especially; sclerotic coats of eyes of a deep-yellow color; pupils dilated; abdomen distended slightly; rigor mortis well marked.

Thorax.—Pericardium contained about six ounces of a straw-colored fluid; about two pints of a similar fluid in each pleural cavity. Firm lateral and diaphragmatic pleural adhesions of left lung. *Lungs*, congested; no œdema; crepitant throughout. *Heart* somewhat enlarged, weight fourteen ounces; muscle dark; coronary vessels engorged. Pulmonary artery and valves normal. Tricuspid valve thickened and rigid, orifice contracted. Right auricle and ventricle slightly dilated and filled with dark-red clots and a chicken-fat clot. Aortic orifice was much narrowed by the stiff, retracted, partly calcified leaflets. The valves could not have effected a sufficient closure. Mitral valve-leaflets diseased, permitting regurgitation; the orifice was narrowed. Columnæ carneæ thickened and rigid. On the endocardium, in the left ventricle, at the apex, and near the mitral valve, small white patches of lymph-like appearance were seen.

Abdomen.—Only a small amount of effusion in cavity. Diaphragm and organs in proper position. *Omentum* normal. *Spleen* diminished in size, very hard. *Pancreas* increased in thickness and weight, cirrhotic. The head was so enlarged that it must have pressed on the common bile-duct. *Gall-bladder* distended and filled with bile; duct pervious. *Liver* diminished to about two-thirds its size, weighing one pound thirteen ounces, left lobe somewhat enlarged, however; firm on pressure, surface unevenly yellow tinged, on section "nutmeg" appearance characteristic. *Stomach* of normal size, in greater curvature mammillated. *Kidneys* normal to naked eye, congested, capsule readily removed. *Suprarenal* capsules thickened, hard, and containing white nodules. *Bladder* and *ureters* normal. On posterior surface of *ureters* a small fibroid tumor. Death was due, no doubt, to cardiac failure. The tricuspid disease was not recognized,—perhaps, as Fothergill has suggested, on account of the amount of blood passing through being too small to develop a murmur; especially so because of the altered mitral and aortic orifices. The tumultuous and

rapid action of the heart may have prevented its detection. That the murmur was not developed on account of the small supply of blood is most probable, for venous pulse and liver pulsation were absent. Disease of the valve permitting aortic regurgitation was not recognized, from the same cause or causes, or it was entirely overlooked. I think in both cases the murmurs were absent, as most careful auscultation was performed.

On microscopical examination the liver presented the characteristics of red atrophy, the kidneys were slightly cirrhotic, the pancreas markedly cirrhotic. Examination of the white patches in the endocardium proved them to be the result of a chronic inflammation, like that of an atheroma.

Dr. FORMAD had found upon examining the pancreas that it was much enlarged. Microscopical examination, however, showed that this enlargement was not due to any neoplasm, but to cirrhosis and marked increase of the interacinous connective tissue. The white patches upon the heart muscle were due to mere thickening of the investing serous membrane. Portions of these patches were slightly eroded. The liver presented a rare condition, —viz., red atrophy. This was most marked around the hepatic venules, where the liver-cells were represented merely by a mass of reddish débris. At the periphery of the lobules the cells were much less affected. These conditions, conjoined with marked cirrhosis, account for the microscopic nutmeg appearance of the organ. The kidneys and the suprarenal capsules were normal.

Dr. BRUEN asked Dr. Formad whether there was any catarrh of the gall-ducts.

Dr. FORMAD replied that he had detected none, the ducts being, however, contracted and obstructed at points.

Dr. MUSSER asked if the patches upon the heart were due to an acute or chronic change.

Dr. FORMAD considered the process chronic.

Dr. HENRY remarked that it was an interesting point in connection with Dr. Formad's report that the lesions due to obstructed circulation were so exclusively confined to the liver. He would naturally expect to find in such a case a marked degree of cyanotic induration of the kidneys.

Differential diagnosis of cerebral embolism and thrombosis in cases of disease of the valves of the heart.

Dr. CHARLES K. MILLS said that some points in Dr. Musser's notes recalled a case which he had recently examined post mortem, and in connection with which he wished to make some remarks on the differential diagnosis of cerebral embolism and thrombosis in cases of valvular disease. The patient was a woman more than sixty years of age. During life he had made the diagnosis of fatty degeneration of the heart, and of aortic, and probably mitral, disease. Dr. Bruen, who saw the case in consultation, concluded that only the aortic valves were diseased. The radial and temporal arteries were markedly atheromatous. She had had three attacks of right-sided paresis or paralysis, dying after the last, which came on suddenly. Post-mortem examination showed extensive calcification of the aortic crescents and degeneration of the heart-walls. The aorta and the cerebral vessels, both large and small, were atheromatous. Centres of softening were found in the motor zone of the cortex of the brain, and also in other regions. Several of the secondary and tertiary branches of the middle cerebral artery were found to be closed, the occlusion being due to disease of the walls of the vessels and the formation of thrombi. In cases like this the diagnosis of embolism is not infrequently made, although the condition found is really thrombosis. He would give the following as good diagnostic points. In favor of thrombosis would be (1) advanced age; (2) evidences of atheroma of vessels; (3) fatty degeneration of heart; (4) a succession of slight attacks of paresis. In favor of embolism would be (1) youth; (2) absence of signs of atheroma; (3) previous history of rheumatism; (4) a comparatively severe attack of paralysis.

He, of course, did not mean to go into a detailed discussion of embolism and thrombosis, but only to call attention to one or two differential features.

Dr. TYSON asked if the urine had been examined for sugar.

Dr. MUSSER, in reply, stated that appropriate tests had been applied, but with negative results.

Dr. TYSON, in explanation of his question, said that we have here hypertrophy of the pancreas,—a condition which Niemeyer, on the supposition that diabetes is due to the presence of an increased amount of pancreatic ferment, says always attends diabetes. This is only one of many instances constantly occurring, which show that such a theory of diabetes is inapplicable,—at least, to most cases.

Dr. HENRY remarked, in reply to Dr. Mills, that his experience had led him to believe that softening of a portion of brain-tissue might occur without complete occlusion of the vessels supplying it. About three years ago he was summoned, early in the morning, to an old gentleman who had awakened to find a loss of power in his left hand. While examining him, the paralysis gradually passed away and returned, and in the course of an hour this intermittent paralysis occurred several times. There was no abnormal cardiac sound, and the kidneys, from previous examination, were known to be healthy. On further study of the case, it was noticed that the paralysis, which continued in this intermittent manner for several weeks, was always at its worst in the early morning, when the

heart was acting most feebly. The superficial arteries were not at all atheromatous, so far as could be decided by the touch; nevertheless, the diagnosis of partially-occluded cerebral vessels, with a slightly-fatty heart, was confidently made. The treatment completely confirmed this theory. A few teaspoonfuls of wine taken before rising in the morning caused an immediate improvement in the morning attacks, and under the continued use of the iodide of potassium in small doses the paralysis disappeared. In about a year a second, more decided attack occurred, this time involving the facial muscles of the left side and, in a slight degree, the left leg. This attack was also recovered from, to a great extent, the only perceptible trace remaining being a certain slowness in pronouncing particular words and a slightly diminished grasp of the left hand. A third attack in June last proved fatal,—about six weeks from its commencement. Its onset was more sudden than either of the two former, but by no means *foudroyant*, and it was accompanied by decided symptoms of cerebral softening. At the same time Dr. Henry had under his care a hospital patient, a woman aged about seventy, whose case was almost identical with the one just outlined, even to the time of the attack and the date of death. An autopsy was obtained, and a softened mass, almost diffluent at its centre, was found occupying the extraventricular portion of the right corpus striatum. The small arteries supplying this portion of the brain (arteriæ corporis striati) were traced from their origin—from the middle cerebral artery—to the softened portion of brain, and, although decidedly atheromatous, were not occluded at any point.

Dr. LONGSTRETH said that he agreed with the remarks of Dr. Mills as to the distinctive points in the differential diagnosis of cerebral embolism and thrombosis, so far as mentioned by that gentleman. He was surprised that one very important differential point had been omitted,—viz., the suddenness of the invasion of the symptoms in embolism in contradistinction to the gradual onset in thrombosis. In cases of embolism, a vegetation becomes detached from the diseased heart-valve, and is carried by the blood-current into one of the cerebral arteries. The immediate effect is to cut off the supply of blood to the vascular area beyond the point where the embolic mass is lodged, and that portion of the brain becomes functionally dead. This process is a rapid one, and, if the area involved corresponds to the motor ganglion, hemiplegia results with a suddenness comparable to that due to cerebral hemorrhage. In thrombosis, on the other hand, the closure of the vessels is effected by a gradual process.

Dr. MILLS could not agree with Dr. Henry if he meant to teach that extensive softening, or, in fact, any softening, of the brain could occur without closure of vessels. Softening of the brain was a process altogether peculiar,—a necrobiosis. In order that the pathological process shall result, vessels somewhere must be *closed*. The vessels may be large, may be of medium size, or may be very small, but occluded they must be before softening can take place. We never find true cerebral softening without complete blocking of some of the vessels going to the part. He even doubted the existence of the so-called inflammatory softening of the brain, except in so far as processes of inflammation might lead to occlusion of vessels. He made this assertion knowing that one school of pathologists held to a different opinion. In the case related by Dr. Henry, vessels were found diseased, and their calibre diminished, but they were patulous. May not some occluded vessels have escaped observation? Even with the greatest care, such as was no doubt taken by Dr. Henry, diseased vessels will sometimes elude us. Numerous nutrient vessels, branches both of the anterior and the middle cerebral vessels, supply the corpora striata. These too are terminal vessels, each supplying a limited area, and not having anastomosing branches. Some of them might readily, in the most careful hands, be broken, torn, displaced, or overlooked. He thought that *hardening* and atrophy of the brain were more likely to result than softening from a poor supply of blood or from a supply of poor blood. He was not without the weight of great authority—that of Hughlings-Jackson, for instance—for such views as he had tried to advance. In connection with a discussion of this kind, the fact that necrobiosis may result from numerous occlusions of cerebral capillaries should be remembered.

Dr. Mills considered the point made by Dr. Longstreth, that paralysis from thrombosis comes on slowly, and that from embolism suddenly, a very good one. He should not have omitted it in his enumeration of differential points. He did not, however, look upon it as absolutely distinctive. Some cases of cerebral thrombosis do at times develop paralytic symptoms suddenly. The degenerative disease of the vessels proceeds slowly, the narrowing of the calibre of the vessel taking place gradually; but the final act of closure, the completion of the blocking, may be practically sudden, and thus give rise to the same shock as occurs in a case of embolism. He might here take occasion to remark that embolism and thrombosis do not *always* induce softening. In a brain examined by Dr. Shakespeare and himself, they had found twenty or more points of closure, but only seven foci of softening in the convolutions. The escape from softening in such cases was due to collateral circulation, which in the cerebral cortex was freer than Duret would admit.

Dr. HENRY agreed entirely with Dr. Mills in regard to the necessity of care in the post-

mortem examination of the brain. His experience as physician to a large hospital had long ago taught him this fact, not only in connection with the brain, but also in regard to every other organ of the body. As concerns the case in question, the centre of cerebral softening having been found, the vessels had been traced from it to their point of origin from the middle cerebral artery. No difficulty whatever had been encountered in making this dissection, the softened brain-tissue being readily and completely removed from the small though rigid blood-vessels. Numerous patches of atheroma were observed in the walls of these vessels, but their lumina were patulous. Dr. Henry thought that a weak heart, in connection with but partially occluded vessels, might lead to cerebral softening. He could on no other theory account for the symptoms of the case to which he had first referred, in which the paralysis was intermittent, in the course of an hour a complete paralysis being followed by an almost complete restoration of power, and this on numerous occasions. Remedies which strengthened the action of the heart, such as wine, caused an immediate improvement in the symptoms; and, conversely, the paralysis was always at its worst when the patient had been the longest deprived of food, and the heart in consequence was acting most feebly,—namely, in the early morning before breakfast. Finally, the symptoms of cerebral softening were completely developed in subsequent attacks. Taking this case in connection with the almost precisely similar one in which an autopsy was obtained, and in which the most careful possible search detected no vascular occlusion, Dr. Henry was so firmly convinced of the possibility of cerebral softening without complete vascular obstruction as not to be shaken in his belief by merely negative evidence.

Dr. LONGSTRETH said that he thought it was supposable that a sudden closure of a large vessel was possible; for example, a cerebral artery where the diseased inner coat suddenly became detached and occluded the calibre of the vessel. Again, a rapidly occurring hemiplegia or unconsciousness in the absence of valvular heart disease might possibly be due to thrombosis, provided the occurrence of a cerebral hemorrhage could be excluded. Cerebral embolism did not occur except in connection with endocardiac or valvular disease, or with atheromatous changes in the large vessels. Sudden hemiplegia did not occur except from cerebral hemorrhage, embolism, or possibly, as in the present discussion, from thrombosis, unless symptoms of other cerebral disease pre-existed; for example, tumors. If heart or vascular disease were absent, embolism could be excluded. In all cases of sudden unconsciousness, therefore, it was a question between cerebral hemorrhage and thrombosis. Several years ago, Dr. Longstreth said, when examining a number of cases of cerebral embolism at the Pennsylvania Hospital, he had consulted the records of medical literature concerning this question, and had not been able to find any well-authenticated cases of cerebral thrombosis. In his personal experience the cases of thrombosis all originated from the sinuses or were of venous character; in these cases, of which he had examined several, the cerebral symptoms were sudden in their onset. Hemiplegia or unconsciousness did not characterize them, although paralysis developed subsequently.

He considered Dr. Mills's language was too weak a characterization of this symptom. The point in regard to the suddenness of the symptom was not only a *good* one, but a *capital* one. Dr. Longstreth said he would like to ask for Dr. Tyson's experience in the matter.

Dr. TYSON agreed with him, but could imagine the possibility of the occurrence of cases such as those mentioned by Dr. Mills.

Dr. LONGSTRETH then asked whether Dr. Tyson knew of any such recorded cases.

Dr. TYSON said that he did not.

Dr. MILLS said that they were both theoretically and practically possible, and he thought that observers had overlooked this fact.

Dr. LONGSTRETH could not see how the condition of vessels could result, such as would lead to complete and sudden closure of a cerebral vessel, without precedent cerebral symptoms having been present, either in their slighter form, as mental feebleness or drowsiness, or in their graver form, such as is due to cerebral syphilis. Until proof of such cases having been observed were adduced, he should continue to doubt their occurrence.

Dr. MILLS said that he had seen more than one patient stricken with paralysis suddenly when he also believed thrombosis was the morbid condition present. He had several times confirmed his diagnosis by autopsies. The case reported by him this evening was one of this kind. Usually, however, prodromata are exhibited in these cases.

Dr. TYSON thought that of course this would be the only proof of Dr. Mills's theory, and hoped that he would at a future time report the cases referred to, upon which he founded the statements that he had made this evening.

Dr. SHAKESPEARE said that, since the field of theory had been entered upon, he could conceive of cases where spasms of the vessels from reflex causes might produce sudden unconsciousness, which would, of course, disappear in due time.

DR. STEVENS, of London, and Dr. Atlee, who have both had an immense experience in vaccination, declare that there has not been the slightest deterioration in the efficacy of the humanized lymph.—*St. Louis Courier of Medicine.*

PHILADELPHIA ACADEMY OF SURGERY.

MEETING OF NOVEMBER 1, 1880.

The President, DR. S. D. GROSS, in the Chair.

(Continued from page 188.)

MASTURBATION IN A FEMALE CHILD OF ONE AND A HALF YEARS.

DR. T. G. MORTON gave the history of a case of apparent masturbation in an infant. The child, now 3½ years of age, a female, had contracted the habit more than two years since. It would sit in a corner and rub its crossed legs together until it exhibited the signs of the venereal orgasm. Treatment by bromides was unavailing, as was the search for a physical cause of the affection. Finally an apparatus was devised consisting of a body-jacket with leather thigh-bands and hooks, so regulated that the child was unable to cross the limbs, and thus was prevented from performing the act. The cause was, in his opinion, cerebral, but he hoped to effect a cure by the apparatus.

Dr. S. D. Gross had seen a similar instance at four years, which passed from notice without a cure being effected by varied treatment.

Dr. S. W. Gross had seen reports of similar cases by Jacobi, of New York, and also in the *Berliner Klinische Wochenschrift.* Some of these had been treated by mechanical appliances to keep the thighs apart.

EXTRACAPSULAR FRACTURE OF THE NECK OF THE FEMUR FOLLOWED BY PERFECT CURE.

Dr. John H. Packard showed a patient who now walked without any apparent limp in his gait, though he had sustained an extracapsular fracture of the femoral neck. The injury was sustained on the 7th of May last, by a fall. The diagnosis was made under ether, and the patient then treated by continuous extension. About the tenth day he was directed to sit up in bed, and to do so for a longer and longer time daily,—the extension being still maintained. Fourteen weeks after the accident, he was at work as usual, at a carriage-factory.

An examination showed a large amount of callus about the seat of fracture. All the motions of the joint were perfect.

CASES OF RETENTION OF URINE COMPLICATED WITH ABSCESS.

Dr. John H. Packard also gave a verbal account of two cases of retention of urine necessitating perineal section. The first patient had, when seen, an abscess of the testicle and stoppage in the flow of urine. The penis and perineum were swollen, and, as it was impossible to introduce a catheter, and there seemed to be danger of rupture of the bladder, Dr. Packard performed perineal section without a guide, and found a greatly distended bladder, which was evacuated by the operation. The operation rendered the patient comfortable, and he is now favorably progressing.

The second case was somewhat similar. The patient had been operated on for stone ten years previously, and presented a perineal cicatrix, which was apparently the cause of the urinary obstruction for which surgical aid had been requested. Extravasation was feared when Dr. Packard saw the case: he was able to draw off a small amount of urine with a small catheter. Very little relief followed this measure, however, and it was observed that there was vivid redness and a puffy condition of the abdomen. On the next day a small rubber guide was passed into the urethra and perineal section performed, when a large abscess was found communicating with a collection of pus between the fasciæ of the abdomen. The bladder could be thoroughly explored with the finger, and seemed merely rugous. No further trouble ensued from retention of urine, but the patient sank and died on the fifth day after the operation, apparently from septicæmia. No autopsy could be had.

SPECIMEN OF FRACTURE AND DISLOCATION OF SPINE.

Dr. R. J. Levis showed a specimen illustrating compression of the spinal cord by the slipping forward of one vertebra on the other, due to tearing of the intervertebral substance and fracture of the processes. The history of the patient is as follows:

Joseph K., aged 40 years, was admitted to the Pennsylvania Hospital on September 30, 1880. He was caught in some way in a coal-slide, but could give no account of the accident, as he spoke no English. On admission, the back was very much contused. A fracture was made out, but not defined, about the first lumbar vertebra. The patient had complete paraplegia from the hips down. Urine was drawn every three to four hours; about a week after admission urine dribbled from the bladder itself. The patient became gradually weaker each day, and died on the night of October 16, from exhaustion.

SECONDARY SARCOMA OCCURRING AFTER AMPUTATION.

Dr. S. W. Gross showed the specimens taken from a child who had died five days previously in convulsions from a metastatic osteoid round-celled sarcomatous growth occupying the temporal region of the skull. The patient had been operated on twelve months previously for periosteal osteoid round-celled sarcoma of the ulna, for which Dr. Gross had amputated at the middle of the arm.

As the case was referred to in the paper on "Sarcomata of the Long Bones," presented at the meeting of the Academy on October 6, 1879,* it was deemed proper to present the specimens at this time.

GUNSHOT WOUND OF THE PENIS PRODUCING URETHRAL FISTULE. By J. EWING MEARS, M.D., SURGEON TO ST. MARY'S HOSPITAL.

P. V., aged 34, was admitted to the wards of St. Mary's Hospital, June 6, 1880, suffering from fistule of the penile portion of the urethra, the result of a gunshot wound of the penis. On admission, he stated that, seven weeks before, he was wounded whilst engaged as an officer of the law in the arrest of a criminal. When he received the wound he was standing in front of his assailant, at a distance of thirty feet, and about ten feet below, the gun having been fired from a window. On examination, it was found that the ball, discharged from a Winchester rifle, had entered the base of the glans penis at a point one-third the distance from the corona to the meatus, and passing through, in a direction slightly oblique, from above downwards, and before backwards, had partially emerged at the under surface just behind the junction of the glans and body; thence, being deflected in its course, it passed backwards to the junction of the penis and scrotum, between the integument and urethra, lacerating the former, entered the septum of the scrotum, and, passing through to the extent of two inches, wounded slightly the epididymis of the right testicle, and emerged at a point two and a half inches from the base of the penis. Continuing its course, it grazed the under surface of the right buttock and passed out through the clothing, clipping out a piece from the lower border of his coat. The hemorrhage following the receipt of the wound was quite copious and soon prostrated him. This was controlled by the attending physician, and sutures were introduced to approximate the edges of the wound of the penis.

On admission to the hospital, an examination was made, and the following conditions were noted. On the upper surface of the glans penis there was an irregular, ragged cicatrix, and on the under surface, at a point just behind the base of the glans, there was an opening one-fourth of an inch in length, leading into the urethra. One-quarter of an inch posteriorly there were two small fistulous tracts, with openings the size of a surgical probe. These communicated with the urethra, being separated from each other by a band of tissue one-fourth of an inch in width. The under surface of the penis was denuded of the integument from the junction of the anterior and middle third to the scrotum, exposing to this extent the fibrous envelope of the corpus spongiosum. On exploring the urethra, a stricture, admitting a small surgical probe, was found three-fourths of an inch posterior to the meatus. During micturition the urine escaped by the fistulous openings.

As a preliminary step to the operation of urethroplasty, which it was decided proper to perform, the stricture was divided and dilated so as to admit a No. 12 bougie, English scale. Following this operation and the efforts at dilatation, a severe attack of cellulitis of the penis occurred. This condition was relieved by treatment, but manifested a tendency to return after each introduction of the instrument. Gradually this was overcome, and an attempt was made to close the fistule by plastic operation. An attack of cellulitis again occurred, and rendered the operation but partially successful, about one-half of the opening being closed. As the patient had suffered severely from the heat and confinement in the hospital, he was advised to return to the country and wait until the approach of cold weather before another attempt at closing the fistule was made.

Gunshot wounds of the penis are of rare occurrence in civil practice, the information given in surgical text-books and treatises with regard to these injuries being largely, if not altogether, derived from military sources. It has been observed that these injuries are rarely uncomplicated, the projectile, either after or before coming in contact with the organ, having wounded the parts which are adjacent. In the "Medical and Surgical History of the War of the Rebellion" (Part II., surgical volume), the author, Dr. Otis, reports three hundred and nine shot injuries of the penis in which it is stated no mention was made by those under whose care the cases occurred of involvement of the urethra. Complications, however, were frequently present, and embraced wounds of the scrotum and testes, perineum and thighs, pelvic walls and viscera. Thirteen and two-tenths per cent. of the cases terminated fatally, the mortality occurring in those in which the complications were of a grave character, involving serious injuries of the femur or of the cavity of the pelvis. Cases of great interest are reported by Drs. S. W. Gross and J. Mason Warren, in which the projectiles became encysted in the cavernous portions of the penis.

Of wounds of the penis involving the urethra, the cases reported in the same volume number one hundred and five. Of this number twenty-two terminated fatally, and, as in the fatal cases above mentioned, the causes of death were due to the grave complications which were present.

Traumatic stricture and urethral fistule resulted in many of the cases reported, the former attending the cicatrization of the wound, owing to its lacerated character. The formation of the latter, as stated, may be caused by extensive loss of substance; partial loss, with urinary infiltration; ulceration due to prolonged maintenance of an instrument in the canal; lodgment of foreign bodies; obstruction of the canal anteriorly to the wound by traumatic stricture. Of the wounds of the urethra, those involving the penile portion are most frequent and at the same time the most intractable; those of the scrotal and perineal portions are rarest and most fre-

quently include the conditions of urinary infiltration.

The resistance offered by the structures of the penis to the projectile, and the remarkable deviations in its course as a result, are well illustrated in the case above reported. It seems almost impossible for a ball having the propelling force of the one which caused the wound in this case to be deflected at a right angle from its course after it had passed nearly through the organ, then traverse other resisting structures, and finally pass clear of the body. It is also to be remembered that the projectile was discharged from a point higher than that occupied by the patient, and, presuming the organ to have been in a flaccid condition and depending, it renders the course taken by it still more remarkable.

In fistules caused by shot lacerations plastic operations are more difficult in performance and less successful in result, owing to the loss of tissue forming the walls of the urethra and adjacent to it. Also, the existence of the stricture complicates the case, and, unless entirely removed by preliminary operation, renders success impossible.

REVIEWS AND BOOK NOTICES.

A Treatise on Diphtheria. By A. Jacobi, M.D. New York, William Wood & Co. 1880.

The limits allotted in this journal to the notices of books, and the multitude of works requiring notice, forbid our giving that detailed attention to the present volume which it deserves. We have read almost every page of it with pleasure and, generally, with instruction. It is divided into nine chapters, which occupy about two hundred and fifty pages of very clear print. The portion of the book to which most physicians, when pressed with the responsibility of some severe cases of the disorder, will first turn, concerns the treatment of the disease. The measures usually adopted by the doctor will be found clearly stated, as also the treatment recommended by various other authorities.

Dr. Jacobi seems to rely chiefly upon the free use of alcohol from the beginning of the disorder, with tincture of chloride of iron and chlorate of potassium, and the employment of local treatment. He calls attention to the fact, not always remembered, that the chlorate is an irritant poison in over-doses, and shows that cases of diphtheria have been killed by it. We think he entirely overestimates the value of small doses of the chlorate. It is clearly established, to our thinking, that the chlorate is nearly free from general action upon the system, and that it is beneficial in scarlet fever, diphtheria, etc., only by its local action. The method in which the chloride is employed is peculiar in the frequency as well as the largeness of the dose. The doctor exhibits the chloride every half-hour, hoping for good from its local influence upon the inflamed mucous membrane. The direct local treatment employed is not severe: the avoidance of any procedure apt to wound the inflamed surface; the free and frequent use of carbolic acid upon the membrane, aided by the use of steam, etc., in the individual case. In some cases, where the application can be strictly limited to a part, a mixture of equal parts of glycerin and carbolic acid is employed as a caustic. In nasal diphtheria free disinfection of the nasal chambers by hourly injections into the nose of carbolic acid water (gr. iv to f℥i) is strongly recommended.

For further details we must refer our readers to the book itself, which we cannot too highly commend. Every part of it shows the possession by the author of an intimate acquaintance with the literature of the disease as well as with the disease itself. The style is excellent,—clear, forcible, and concise. We have never read any article or work upon diphtheria so satisfactory as the one upon whose completion we congratulate Dr. Jacobi with the sincerest of good wishes.

Ophthalmic and Otic Memoranda. By D. B. St. John Roosa, M.D., and Edward T. Ely, M.D. Revised Edition. Small 12mo. Pp. 298.

We have rarely seen so small a book embracing so much. It possesses, in addition, a long train in the shape of a copious glossary and index. Evidently, the labor of preparing such a work was too much for *one* author. He prudently withheld from the attempt until a second came to his assistance. Notwithstanding the authors' avowal that the book is not designed to meet the wants of those seeking *primary* knowledge in the specialties of which it treats, it will of necessity be classified with ponies and coaches. We have had a surplusage of such books in general medicine and surgery, and are sorry to see the specialties invaded by them.

The Compend of Anatomy. By John B. Roberts, A.M., M.D. Philadelphia, C. C. Roberts & Co.

This is a good book of its kind, but we should like to see something more sterling from its author. Dr. Roberts is a man of promise, and should not waste his time in writing compends for "preparing students for examination." Such work has never given genuine reputation to any teacher who has gone into it, and it has never been of much use to humanity.

Hygiene and Sanative Measures for Chronic Catarrhal Inflammation of the Nose, Throat, and Eyes. Part I. By Thomas F. Rumbold, M.D. St. Louis, George O. Rumbold & Co., 1880. Pp. 166.

Dr. Rumbold informs the reader, in the

preface of this manual, that he had been early convinced that the successful management of catarrh depended upon the faithful observance of the laws of health by the patients themselves. The book is an outcome of the necessity of such observance. It appears to be a summary of rules designed for the laity, and, as such, needs no special introduction to the profession. To spread the knowledge that a book exists for the physician to recommend to sufferers from catarrh is evidently the main object Dr. Rumbold has in seeking a notice at our hands. We can say, in a word, that the rules are good and are well worth following by all.

MEDICAL HERESIES HISTORICALLY CONSIDERED. A SERIES OF CRITICAL ESSAYS ON THE ORIGIN AND EVOLUTION OF SECTARIAN MEDICINE. By GONZALVO C. SMYTHE, A.M., M.D. Philadelphia, Presley Blakiston, 1012 Walnut Street.

Professor Smythe has succeeded in writing a brief, clear, and interesting sketch of the evolution of medical eccentricities, and of modern homœopathy, its facts and fallacies. We commend the work, a brochure of 225 pages, to those desiring information on the subject. We sincerely wish the laity could be induced to peruse it.

GLEANINGS FROM EXCHANGES.

OPIUM-POISONING SUCCESSFULLY TREATED BY ATROPIA HYPODERMICALLY.—Dr. J. W. Breedlove (*Virginia Med. Monthly*, December, 1880) was called to a case where eight to ten grains of morphia had been taken at a single dose an hour and a half previously. He at once gave an emetic dose of salt and mustard (both being at hand), followed by copious draughts of warm water, with the twofold object of diluting any unabsorbed poison and facilitating emesis. In about fifteen minutes, no vomiting having occurred, he gave about thirty grains of ipecac, and this, with the aid of titillation of the fauces, produced free vomiting in about five minutes more. The peripatetic and perturbating plan was then adopted, as also the free use of strong coffee, and cold water applied to the face and head. An hour later, at 8 P.M., the narcotism growing deeper and the symptoms becoming more alarming, he injected hypodermically 1-96th of a grain of atropia; in half an hour 1-48th of a grain was administered, and at 9.30 and 11 P.M. this dose was repeated, the use of strong coffee and cold affusions being continued at the same time, the patient being assured that her safety depended on her not giving way to the desire to sleep, thereby securing to some extent her co-operation. At 4.30 A.M. the symptoms were much improved, it requiring but little continued effort to attract her attention. At 8 A.M. the patient had so far improved that the doctor acceded to her request to lie down and take short naps. Not until after the administration of the last dose of atropia did the pupil begin to manifest its mydriatic influence. From this time improvement was progressive; but convalescence was slow, owing to extreme nervous prostration.

COMPARISON BETWEEN THE THERAPEUTIC VALUE OF FREE PHOSPHORUS AND THE HYPOPHOSPHITE SALTS.—Dr. J. Ashburton Thompson, well known for his researches on the action and use of free phosphorus, writes to the *British Medical Journal* of October 30 to controvert in part the views of Dr. Frederick Churchill as to the high therapeutic value of the hypophosphites as a form of phosphorus. He says, "Should the former be substituted for the latter under the impression that their action is identical, disappointment will be experienced in the effects produced in many cases, but more especially in many cases of neuralgia, in cases of insomnia the result of nervous exhaustion (in which it is desirable to avoid the use of narcotics if immediate relief can be procured by other kinds of medicine, as it may be procured by free phosphorus), and in all cases of imminent death under the typhoid condition."

Having tried the hypophosphite salts, Dr. Thompson has now almost entirely relinquished them in favor of hypophosphorous acid. This acid, of which the dose is one, two, or three drops for infants, five drops for adolescents, and ten drops for adults, given every four hours, Dr. Thompson has been brought to regard as a valuable means of treating all cases of disordered nutrition, whether the result of chronic or acute febrile disease. It may be administered in a variety of combinations, and he has been led to prefer it to the alkaline salts because he has found its effects more promptly manifested, productive of more permanent results, and withal more generally useful.

CHLORATE OF POTASSIUM IN THE HEMORRHAGIC DIATHESIS.—Dr. Alexander Harkin (*British Medical Journal*, vol. ii., 1880, p. 700) continues to extol the virtues of this drug. He gives several cases in which its success in restraining hemorrhage of different kinds was decided. In one of these, hemorrhage from the mucous membrane of the rectum, he prescribed rest and a mixture of one ounce of chlorate of potassium and twenty ounces of water: dose, one ounce three times daily. After the first day the patient began to improve, and by the third day every trace of the disease had disappeared. In a case of hæmophilia with habitual and often virulent epistaxis the same treatment was employed, only with the addition of one drachm of the tincture of the chloride of iron per dose. A fortnight later the patient was well. In a case of renal hemorrhage the same combination proved effectual after many remedies,

and even the tincture of iron alone, had proved without avail. Two cases of purpura hæmorrhagica, due to low diet and a scorbutic condition, are also reported by Dr. Harkin as cured by a similar treatment. Cases of menorrhagia, hemorrhage from the womb, hæmatemesis, and hæmoptysis were all treated successfully with the chlorate; and, though Dr. Harkin may be too sanguine in his advocacy of this remedy, it certainly deserves to be remembered among our means of controlling hemorrhage.

Apparent Death as a Result of Asphyxia.—Medical journals occasionally inform us of wonderful resuscitations brought about by the persistent use of artificial respiration; but two, lately reported to the Academy of Sciences, Paris, by Dr. Fort, Professor of Anatomy in the Ecole Pratique, are especially noteworthy, and teach us to persevere in any efforts we may make to bring back signs of life. In the case of a child three years old, who had already been placed in the shroud, Dr. Fort commenced the use of artificial respiration three and a half hours after apparent death. After four and a half hours of steady work the child was brought back to life. The other case was that of a drowned man, who had been under water for twelve minutes before the body was recovered. Artificial respiration was commenced an hour afterwards, and after being kept up for hours the man was restored to life. The report of the meeting of the Academy does not give the details of the child's case before the appearance of the apparent death, nor what prompted the doctor to commence the artificial respiration. —*Medical Press and Circular.*

Reprehensible Practice.—A correspondent of the *Druggist's Circular* writes as follows: "A few weeks since, a young man suffering from toothache asked a druggist for something that could relieve him. The druggist dissolved eighty grains of chloral hydrate in one ounce of syrup of ginger, gave one drachm of it, undiluted, to the patient, and wrote on the label, 'A teaspoonful every half-hour till relieved.' The patient had six doses as directed, when he was taken with convulsions, palpitation of the heart, and finally unconsciousness, attributed by regular physicians, then called in, to an overdose of chloral. The consequence was that the patient was sick for two weeks from the effects of the dosing, and claims that the druggist did wrong and should pay the doctors' bill. The druggist claims that he was not wrong, and should do the same thing again. Is the druggist culpable or not?"

The editor replies at once, and plainly, that the druggist is guilty of criminal imprudence; and we are convinced that our readers will agree with him in this opinion.

Essence of Winter-Green in Purulent Cystitis.—The essence of winter-green, more used in perfumery than in pharmacy, is, according to the *Journal de Médecine et de Chirurgie pratiques*, used by M. Périer, of the St. Antoine Hospital, in the treatment of purulent cystitis. It is a powerful antiseptic, of a penetrating but not disagreeable odor, and non-irritant. Though its price is high, this does not form a bar to its use, as it is given in very small doses. The essence of winter-green is procured from the *Gaultheria procumbens*, a North American shrub. Chemically, the essence is called salicylate of methylene, or methylsalicylic ether: it is only slightly soluble in water. Dr. Périer employs the following combination: essence of winter-green, six grammes; tincture of quillaya saponaria, thirty grammes; water, one litre. This forms an excellent fluid for injecting into the bladder, for washing wounds, and for some simple dressings.—*Medical Press and Circular.*

Treatment of Choleraic Diarrhœa by the Hypodermic Injection of Morphia.—Mr. W. Hardman says (*Lancet*, vol. ii., 1880, p. 538) that choleraic diarrhœa can always be immediately stopped by the administration of morphia hypodermically. If severe diarrhœa have persisted over two hours in spite of the administration of morphia and opium, hypodermic injection of morphia should be at once resorted to. The treatment is absolutely free from danger, even if albuminuria or temporary suppression of urine be present. In severe cases obstinate vomiting may persist for twelve to forty-eight hours after the purging is stopped; but this need not occasion any anxiety: it is the purging that kills.

Statistics relating to the Seat of Chancrous and Chancroid Ulcers in Women.—Dr. Razumoff tabulated 1374 cases, treated in one of the Moscow hospitals, as follows: ulcers were seated on the uterine cervix in 117 cases (8.5 per cent.), 13 of this number being chancres with subsequent general infection; 664 on large and small labia; 272 at the vaginal entrance and between the mystiform caruncles; 176 on the posterior commissure; 60 on the perineum; 55 about the anus; 26 on the anterior commissure; 3 in different parts of the vagina, and 3 on the meatus urinarius.—*Meditz. Obozrenie*, p. 360, May, 1880; *New York Medical Record.*

Treatment of Excessive Perspiration of Hands and Feet by Faradic Current. —As this symptom is due to disordered functional activity of peripheral nerves, Dr. Gordon was led to study this particular condition, with the following results. The tactile and faradic sensitiveness of these parts is diminished; their temperature is lower. Systematic faradization controls the perspiration, and corresponding to the effects of treatment the above two conditions are relieved.—*Vratch.*, 1880, No. 20; *New York Medical Record.*

Atropia as a Substitute for Morphia for the Relief of Pain.—Dr. Wrightson, of Newark, New Jersey, reports a case of cholera

morbus in which the intense pain was instantly relieved by one-eightieth grain of atropia hypodermically, after the failure of thirty minims of Magendie's solution of morphia. The patient was on board of a pleasure-yacht, and the atropia, Magendie's solution, and a hypodermic syringe composed the doctor's armamentarium. — *Maryland Medical Journal*, September 1; *New York Medical Record.*

MISCELLANY.

FILARIA DISEASE.—The parasitic theory of the causation of elephantiasis has been subjected during the last two years to a considerable amount of criticism, favorable and unfavorable. It has been accepted by some, and those the best acquainted with tropical disease, as supplying the key to what before was mysterious and a sealed book; others, again, have suspended judgment in the matter, considering the evidence not yet complete; while a third section, including eminent pathologists, such as the late Dr. Tilbury Fox, deny it altogether. In the eighteenth issue of the valuable half-yearly medical reports of the Chinese Imperial Maritime Customs, just received from Shanghai, Dr. Manson, of Amoy, who is well known as one of the most earnest workers in this field of pathology, gives a very striking account of his further researches into the question. Perhaps the most remarkable of his results has been the discovery of the periodicity observed by the embryo of Filaria Bancrofti in the blood.

He observes that it had always seemed strange to him that the filaria sanguinis hominis had escaped observation in the blood until Lewis found it there in 1872: "One would think there were hundreds of workers in India, and in different parts of the tropical world, who must have searched the human blood in the aggregate thousands of times; and, notwithstanding this, the parasite, which in some places is present in every tenth individual, was overlooked, or never found, for so many years." The explanation of this Dr. Manson now offers. Most workers with the microscope pursue their investigations during the hours when the light is good,—*i. e.*, during the day. Dr. Manson shows that this is the wrong time to search for filariæ. Finding that different results were obtained by his assistants according as they worked during the day or after dark, he made a systematic examination every four hours of several patients, with the view of ascertaining if this periodicity was maintained in every case. Examination of the patients in this way showed that, unless there is some disturbance, as fever, interfering with the physiological rhythm of the body, filaria embryos invariably begin to appear in the circulation at sunset, and their numbers gradually increase till about midnight; during the morning they become fewer by degrees, and by nine or ten o'clock in the forenoon it is a very rare thing to find one in the blood. Until sunset they appear to have completely deserted the circulation, but with the evening they come again, to disappear in the morning, and so on with the utmost regularity every day, and from day to day. The circle is completed every twenty-four hours, and there are no longer spells of absence than from morning to evening. For the meaning of this Dr. Manson thinks we have not far to look: "The nocturnal habits of the filaria sanguinis hominis are adapted to the nocturnal habits of the mosquito, its intermediary host, and form only another of the many wonderful instances of adaptation so constantly met with in nature."

The conclusions at which Dr. Manson arrives, after his study of the subject, are the following, which deserve serious attention. The parent filariæ live in the lymphatics. This is proved by their young and ova being found there even when absent from the blood. They do not live in the glands, but in the lymphatic trunks on the distal side of the glands. (Lewis and Bancroft found them in tissues some distance from any glands.) They are oviparous. The eggs are carried by the lymph-current to the glands; and, being too large to pass ($\frac{1}{502}'' \times \frac{1}{750}''$), they are arrested there till hatched. After hatching, the free embryo passes along the lymph-vessels and enters the general circulation. Resting in some organ during the day, it circulates with the blood during the night; whence the mosquito abstracts it and acts as its intermediary host. In certain cases the ova or embryos produce obstruction of the lymph-circulation through the glands, either directly by their size, or indirectly by causing inflammation. If the obstruction be partial, varicosity of glands and of afferent lymphatics results; but by means of the anastomoses the lymph-circulation is continued, carrying the embryos with it into the blood. Lymph-scrotum, or chyluria, or varicose groin-glands, with hæmatozoa, are therefore the symptoms of partial obstruction of the lymphatics. If the obstruction be complete, one or other of two things happens. *a.* The accumulating lymph so distends the vessels that they rupture, and a lymphorrhagia results, which is more or less permanent. In this case, the lymph does not quite stagnate; but, being able to circulate, though in a retrograde manner, it remains fluid. The symptoms of this form of obstruction are, therefore, lymphorrhagia from scrotum or leg, varicose glands, and filaria-embryos in glands, and perhaps in discharged lymph, *but none in the blood.* *b.* If the lymphatics fail to rupture, there is a complete stasis of lymph, and excessive accumulation in the tissues on the distal side of the glands; solidification of the glands and

tissues, and elephantiasis, result. No embryos are found in the blood, as none can pass the glands; and the parent worm or worms probably die choked, so to speak, by the stagnant and organizing lymph and their own young. Consequently, in pure elephantiasis, as a rule, no embryos can possibly be found in the blood or in the lymph of the glands.—*British Medical Journal.*

MEDICAL NIGHT-SERVICE IN PARIS.—The statistics of the Medical-Night Service in Paris for the period from July 1 to September 30, 1880, show 1570 visits to have been paid by the physicians. The table of diseases treated is interesting reading, and should be instructive to the newly-fledged practitioner who is well posted in the diagnosis and treatment of progressive pernicious anæmia or yellow fever, but is a little nervous at fear of being unequal to some sudden "emergency case." The commonest cases which the Night Medical Service was called upon to treat were as follows: Gastro-intestinal troubles, 156 cases; "neuroses," 93; accouchements, 90; hemorrhages from external or internal causes, 89; cerebral affections, —paralysis, 87; angina and laryngitis, 79; cholerine, 76; wounds and contusions, 71; hepatic, nephritic, and lead colic, 67; eclampsia-convulsions, 65; neuralgia, 63. In 51 cases death had occurred before the arrival of the physician. The average number of visits per night was 17; 36 per cent. of the patients were men, 49 per cent. were women, and 15 per cent. were children under three years of age.

RECTAL ALIMENTATION.—At the meeting of the French Association for the Advancement of Science at Rheims, M. Catillon read a paper on "Alimentation by the Rectum," in which he stated that he had fed two dogs during two months with injections of eggs. The first, which had eggs only, lived with difficulty, with considerable loss of weight; the other, in which the injected eggs were mixed with glycerin and pepsin, lived in an apparently normal manner, weight and temperature being constant. After thirty-seven days, the pepsin having been stopped, the animal lost weight, and the temperature fell from 102° Fahr. to 99° Fahr. It is therefore apparent that, in order that nutrition should be properly performed by the intestine, digestive ferments must be associated with the food, —that is to say, they must be transformed into peptones.—*Medical Press and Circular.*

SULPHATE OF ZINC IN DIGESTIVE DERANGEMENTS.—According to Niewodniczanki, this salt may be advantageously employed in place of nitrate of silver in affections of the digestive organs (*La Presse Médicale Belge*). The sulphate of zinc is less easily decomposed, is better tolerated, and seems very active. It has been employed with success in acute and chronic affections of the stomach and in gastralgia; the addition of codeia or opium to the sulphate of zinc is unnecessary, for the salt is itself calmative. It is given in doses of 6 to 10 centigrammes a day. It is also useful in diarrhœa.—*Medical Press and Circular.*

DR. CARL SEILER, the well-known laryngologist, of this city, will spend some time this winter, beginning January 1, at the St. James Hotel, Jacksonville, Florida. Physicians who have cases going to Florida requiring topical treatment of the larynx can refer them to Dr. Seiler with entire confidence that they will receive the best attention.

FORGOTTEN BY DEATH.—Old Prof. Chevreul, aged ninety-five, has just completed that course of forty lectures on chemistry for which he was so widely advertised a few months ago. As his father lived to be one hundred and five, the old gentleman may yet lecture the century out.

DR. THOMAS WOOD, of Cincinnati, died November 21, from blood-poisoning received by attending with chapped hands the wounded in the recent railroad accident.

THE *Virginia Medical Monthly* will be published as a daily bulletin during the sitting of the American Medical Association at Richmond, Virginia, May 3–7, 1881.

DR. L. WOLFF contributes to the *Pharmacist* a paper on "Pharmacocatagraphologia," which expressive word is supposed to mean the art of writing prescriptions.

THE recent hurricane in Jamaica damaged or destroyed some 10,000 cinchona-trees and over 400,000 seedlings.

THE Medical Committee of Middlesex Hospital report, after long trial, that Chian turpentine is useless in cancer.

SIR BENJAMIN BRODIE, son of the famous surgeon, professor of chemistry at Oxford, and author of a number of scientific works, has just died.

ST. MARY'S HOSPITAL, of this city, has opened an eye and ear department.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM DECEMBER 12 TO DECEMBER 25, 1880.

BAILY, J. C., MAJOR AND SURGEON.—Granted leave of absence for one month, with permission to leave the limits of the Division and apply for one month's extension. S. O. 188, Division of the Pacific and Department of California, December 13, 1880.

HEIZMANN, CHARLES L., CAPTAIN AND ASSISTANT-SURGEON.—The extension of his leave of absence granted him October 30, 1880, from A. G. O., still further extended two months. S. O. 268, A. G. O., December 18, 1880.

KANE, J. J., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty at Fort Cummings, and assigned to duty as Post-Surgeon at Fort Union, New Mexico. S. O. 153, District of New Mexico, December 13, 1880.

BENHAM, R. B., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Relieved from duty at Fort Snelling, Minn., and assigned to duty at Fort A. Lincoln, D. T. S. O. 165, Department of Dakota, December 8, 1880.

PHILADELPHIA, JANUARY 15, 1881.

ORIGINAL COMMUNICATIONS.

CHLORAL HYDRATE.

BY H. H. KANE, M.D.,
New York.

ARTICLE VI.

CHLORAL DELIRIUM.—CONTRA-INDICATIONS.

CHLORAL DELIRIUM.—The delirium from chloral may be of three kinds: 1st, from small doses, disappearing when a little more chloral is given; 2d, from large doses, persisting until some of the chloral is eliminated; and 3d, that which occurs when the drug is suddenly withdrawn after its use for some time. One or more of these three forms have been seen by Drs. J. M. Nordlin, Rome, Ga.; L. C. Herrick, Woodstock, Ohio; J. B. Treadwell, Boston, Mass.; N. C. Husted, Tarrytown, N.Y.; J. N. Lawson, Silver Creek, Miss.; C. H. Hunt, Stanwood, Iowa; W. P. Bolles, Dorchester, Mass.; J. P. Anthony, Sterling, Ill.; John Dixwell, Boston, Mass.; R. E. Sutton, Rome, N.Y.; J. C. Hoffman, Chicago, Ill.; D. N. Kinsman, Columbus, Ohio; E. H. Coover, Harrisburg, Pa.; R. V. Davies, Roxton, Texas; Allison Maxwell, Indianapolis, Ind.; De Forrest Willard, Philadelphia, Pa.; Dr. Waters;* John Hurdsfield, New York City; G. W. Chamberlain, Hartford, Conn.; George M. Beard, New York City; A. P. Brown, Jefferson, Texas; J. P. Landis, Hollidaysburg, Pa.; D. M. Cool, Chicago, Ill.; George W. Elerick, Hickory, Iowa; C. H. Hughes, St. Louis, Mo.; John B. Squier, Sulphur Springs, Ohio; Stephen Rogers;† Francis Goolden,‡ of Maidenhead; J. M. Lewis, Kosciusko, Miss.; C. W. Earle, Chicago, Ill.; J. D. McCleary, Indianola, Ind.; W. H. Travers, Providence, R.I.; George W. Avery, Hartford, Conn.; E. L. Partridge, New York City; C. H. Greenough, New York City; E. Brallier, Chambersburg, Pa.; J. M. Pace, Dallas, Texas; George W. Elliot,§ Bouchut,‖ and many others. The following interesting letter is from Dr. J. A. Ingles, of Morea, Ill. It is a type of the severe cases of chloral intoxication:

"In regard to the case of chloral intoxication, I would briefly say that J. S., laboring under fits of ague, came to my office May 17, 1879, having a little fever and a distressing pain in his head. Said he wanted something to relieve his head and he would wear the chills out. I gave him about twenty-five grains (perhaps thirty, as I fail to remember now) of chloral, dissolved in a little water. In ten minutes he wanted to lie down. Said his head was better, but he felt very queer and light-headed. I took him into a room and helped him to lie down, with instructions to keep quiet and take a nap, after which he certainly would feel better. I watched him a few minutes and left him, as I thought, asleep; but he afterwards said he was not. I turned my attention to something else, but did not have long to wait until I heard a noise as of some one falling out of bed, but in reality he had jumped out, and was trying to climb the walls of the room. He imagined he was riding horseback, and expressed it as going like 'white lightning.' He said he could not see, and wanted to know what made it so dark, this being about 10 A.M. a bright day. His eyes had a glassy appearance, lids about half closed, the pupils were contracted, pulse quick and wiry, muscles rigid and tense; for a short time, perhaps five or ten minutes, complained of freezing. In half an hour he was sweating profusely, when he became quiet and dropped off into a drunken sleep. His conversation during the excitement was that which is generally characteristic of persons under the influence of liquor. He slept perhaps three hours, and awakened free from pain, but very much exhausted. Ate a pretty hearty supper, considering his debilitated condition, but has been enjoying better health than previous to his chloral intoxication. Has not had return of chills."

Here again is that sudden loss of sight which occurred in Dr. Chamberlain's case, and which is quite similar to that described in Article V. In both cases there were violent delirium and hallucinations.

Mauriac¶ relates several cases of very violent chloral inebriety, in two of which there was bleeding from the nose. These

* London Lancet, May 4, 1872.
† New York Medical Record, 1871, p. 379.
‡ Practitioner, 1870, p. 191.
§ (Lancet) Druggists' Circular and Gaz., February, 1870.
‖ Archives Générales, vol. ii., 1869, p. 755.

¶ Gazette des Hôpitaux, 1870, p. 382.

patients were all under treatment for venereal diseases at the Hôpital du Midi.

Dr. S. S. Boyd, of Dublin, Indiana, writes me of the case of a very intemperate man of nervo-sanguine temperament: "He was well educated and talented, but a physical, moral, and mental wreck. A portion of the bones of his cranium had been removed on account of syphilis. While here he suffered at times from neuralgia of face and scalp. To allay these symptoms I prescribed for him twenty-grain doses of chloral, which always gave him relief. Finally he would procure chloral from a druggist and take it without my advice.

"One day he and a friend took a ride into the country, starting at 1 P.M. Before leaving town he bought two hundred and twenty grains of chloral and dissolved it in eight ounces of water. Before their return, at five the same afternoon, he had taken all but about a half-ounce of the fluid, or over two hundred grains of chloral.

"He was ravingly delirious when he returned to town, wanted to kill the friend who accompanied him, but, as he was so weak that two men had to support him to get him to bed, he was not very dangerous. I administered to him one-half grain of sulphate of morphia. In a short time he was asleep, and slept a kind of drunkard's sleep all night."

Prof. Henry M. Lyman, of Chicago, Ill., writes me of a lady who took through mistake ninety grains, in divided doses, in the course of one night. She was for a short time (half an hour) delirious, swearing and shaking her fists at her friends, though naturally a very amiable and religious person. She experienced no bad effects the next day.

Dr. J. A. Miller,* of Williamsburg, Ky., has frequently seen chloral produce intoxication analogous to alcoholic inebriety, being more likely to act in this way when the person has been previously slightly stimulated.

A case of severe delirium tremens, after stopping chloral which had been used for a year, occurred in the practice of Prof. Da Costa, and is reported by Dr. Frank Woodbury.†

A similar case is reported by Elliot,‡ of London.

In many instances delirium does not follow the abrupt stop in the prolonged use of chloral. Such cases are reported by W. R. D. Blackwood,§ Laurence Turnbull,‖ Bidlack,¶ and Lee.**

Occasionally chloral seems to aggravate existing delirium.

Drs. Fraser and Muirhead†† have used chloral in a large number of cases, and with very satisfactory results, especially as regards its hypnotic action in fever. They found that when violent cerebral excitement was present an ordinary dose was apt to increase it, while a double dose sufficed to allay it and produce sleep.

Grainger Stewart‡‡ observes that in one or two cases he had seen distressing symptoms follow the use of chloral. In one case temporary insanity had occurred, accompanied by delirium, the patient fancying he saw rats and other animals running about him. He had no delirium previously.

F. C. Shattuck, Boston, Mass., writes me that he believes it makes nervous and hysterical women wilder instead of calming them.

Obet§§ seems to think that this delirium and "nervous irritation" are due to impurities in the drug. This is also the opinion of Liebreich,‖‖ who, finding delirium and eruption in one or two cases, used another and pure preparation, when no such results followed.

This may be the case in some few instances, but that it is so in the majority I do not believe. I have seen wild delirium from a perfectly pure preparation of chloral in small doses.

Dr. Malcolm McLane, of this city, writes me that he has seen delirium supervening upon a compound fracture greatly aggravated by chloral.

Several of my correspondents claim that the delirium of delirium tremens is sometimes aggravated and continued by the use of chloral, all delusions, etc., disappearing on stopping the drug.

A. P. Hayne, San Francisco, writes me as follows: "Bromide and chloral seem to produce delirium in some cases when long continued; ceasing when chloral is stopped and bromide given *alone*. There

is no doubt but that if given beyond a certain time it will create the visions which it is generally given to overcome. Patients give minute details of what they saw. In these cases all symptoms of delirium tremens had passed away, and medicine was given for persistent insomnia. Lasted from two or three days to ten days in one case."

The doctor, having charge of a home for inebriates, speaks intelligently.

Mr. Pugin Thornton relates the particulars of a case of delirium tremens where eight drachms of chloral hydrate were administered within thirty-three hours and a half. The delirium was not relieved thereby: on the contrary, the patient recovered as soon as the chloral was stopped.*

Dr. Horatio C. Bigelow, of Washington, D.C., writes me that he observed, in one instance, in a hypochondriac, who was given chloral, exaltation of the ideo-motor centres, followed by delirium and subsequently maniacal excitement.

Dr. De Forrest Willard, of Philadelphia, believes that combining the bromide of potassium and morphine with chloral to a certain extent prevents the development of delirium and hastens sleep.

Chloral given to patients who have been abruptly broken from the use of morphia or opium sometimes produces wild delirium, at times amounting to acute mania.†

TETANUS AND CONVULSIONS.

Dr. G. W. Chamberlain,‡ of Hartford, Conn., saw slight tetanic spasm in one case after the use of this drug, as follows: "I gave a dose of fifteen grains to induce sleep in a case of typho-malarial fever. A young man aged 28, of what are called fast habits, never had had any specific disease. In ten minutes after taking it his face and neck were strongly flushed and the muscles of the jaw stiffened. After they relaxed there were several attacks of severe twitching of the muscles of the jaws and face. Brandy hypodermically was of the most service here."

Dr. C. H. Hughes, of St. Louis, Mo., writes me that he has seen one case where there was temporary trismus after the use of chloral.

Regarding convulsions, Dr. C. A. Bryce, of Richmond, Va., writes me, "I have seen chloral produce slight convulsions at the commencement of its use. I now recall a case occurring in my practice some eight years ago, in which I was sent for to see a lady who was suffering terribly from a 'nervous headache,' to which she had been subject for years. I gave her fifteen grains of chloral. In ten minutes her face became almost purple; she passed off into a *convulsion*, from that into a sweet sleep, and had *no return of headache* for years. She had formerly experienced an attack every week or ten days."

From the few cases here detailed and more to be found in literature, it is evident that chloral rarely produces convulsions or tetanus, certainly not so often as morphia, especially when it is given subcutaneously.§

CONTRA-INDICATIONS.

The very formidable list of cases where poisoning, syncope, and death have occurred from the use and abuse of chloral teaches us very forcibly that, if we are to give the drug at all, we should make ourselves thoroughly acquainted with those conditions, hereditary or acquired, in which chloral is either not well borne or dangerous.

The contra-indications to the use of the drug as originally laid down by Liebreich are as follows:‖

1. Extensive destruction of the mucous surfaces of the *primæ viæ*. If used at all in such cases, it must be given well diluted with mucilage; or it may be thrown into the rectum.

2. Arthritic conditions are unfavorable, unless the blood be first rendered alkaline.

3. In typhus, if given, it should be in small doses.

4. In affections of the circulatory apparatus, especially valvular and other serious diseases of the heart, small doses should be used.

5. It is contra-indicated in hysteria, in which it often increases and fixes the condition of excitement. This, Professor Liebreich considers inexplicable.

6. Whether or not it is contra-indicated in icterus remains to be seen, it having been so asserted.

The very extensive use of the drug in the past ten years has taught us that Dr. Liebreich's conclusions are subject to con-

‖ (The Doctor) New York Medical Record, 1872, p. 106.

siderable modification. In the main, however, they remain about the same.

As regards the second clause, Dr. John W. Ogle* and several of my correspondents report that they have used the drug in this disease, and that it did not require any other than the ordinary dose to produce the desired effect. Dr. Farquharson,† however, agrees with Dr. Liebreich on this point, as he himself has found that in acute rheumatism large doses of chloral have not only not done good, but have even caused delirium. Mr. Brudenell Carter, during the discussion (case of poisoning given by Mr. Hulke), wished to know whether there was really sufficient evidence of diminished alkalinity of the blood in rheumatism. A gouty patient of his had told him that the discovery of chloral hydrate was to him an untold source of bliss and happiness.

Dr. A. A. Smith,‡ of this city, finds that chloral acts better in rheumatism after full doses of the alkalies. He thinks that when the urine is alkaline the drug will be found to act rapidly and efficiently, and would take the reaction of the urine as an indication for the amount necessary to use.

With reference to its use in typhus and typhoid fever, it must be said that here too it has received an extended trial, and without producing any very marked evil effects and much good. One case where ten grains produced decided trouble is given in Article IV. Dr. Russell, of Glasgow, Scotland, has experimented with it largely in reducing the temperature in fevers.§ Dr. J. C. Neall,‖ of Deadwood, D.T., has used it in over forty cases of typhoid fever with good result, saying that he has not yet lost a case. Like testimony is given by many others.

Dr. Smith states that he has found that smaller doses are required to produce the desired effect in those fevers where there is a hyperalkaline state of the blood. In one instance, a case of typhoid fever, ten grains by the rectum sufficed to produce sound sleep.

No one will for a moment question the necessity for great care in the use of this drug in rheumatism, gout, typhus, and typhoid fever, for in all these diseases there is a weak condition of the heart after organic cardiac disease, especially in gout and rheumatism, as also disease of the kidneys. It is likely that the danger from fair-sized doses, in these diseases, is due more to the condition of the heart than to the lessened or increased alkalinity of the blood. If acidity or alkalinity has anything to do with the matter, its effect is probably exercised while the drug is in the stomach.

As to the danger of using this drug in diseases of the heart and arteries, it is undoubtedly great, and the utmost caution must be displayed if it is to be used at all.

Dr. Da Costa,¶ in his Toner lectures, says, "Not only in cases of cardiac adynamy, but in other cases where an enlarged and powerful ventricle is faltering before a tight stenosis, chloral is contra-indicated, as it has been found, under these circumstances, to produce a paralyzing effect upon the heart of a most undesirable character."

This, says Dr. MacDonald, may be obviated by using digitalis at the same time.

Dr. J. W. Parsons,** of Portsmouth, N.H., has given it in cases where there was serious valvular trouble, without any ill effect. Still, he does not advise its use where these affections exist.

Dr. Habershon†† had most alarming symptoms from thirty grains of chloral in a case of aneurism of the thoracic aorta. The patient became unconscious at once; face and hands livid and cold; breathed only at long intervals; recovered after five hours. Dr. Habershon believes chloral has a tendency to produce pulmonary congestion, and that it should never be given in bronchitis or pneumonia.

Dr. A. E. McRae‡‡ says, where there is valvular disease of the heart, he has always found it is rejected immediately. He says that Drs. Fuller, Crichton-Brown, and Dunlap, of Jersey, agree with him on this point: their patients kept the draught down and the bad symptoms appeared.

Dr. W. H. Judson, of Wauregan, Conn., writes me of the following interesting case. It presents the peculiarity that inhalations of amyl nitrite seemed to aggravate the woman's condition.

"Woman, 35; two children; organic disease of heart. Called in for neuralgia of trifacial. System free from drugs at time chloral

* Practitioner, 1870.

‡‡ Edin. Med. Jour., 1871.

was given. Gave ten grains or less, certainly not more. *Instantaneously* dropped as though dead; certain blanched, deathly look to countenance, but pulse was full but slow (say 50); no strength to move her limbs or body for over an hour. Roused up in about five minutes after collapsing, with the remark, 'I am dying.' Assured her she was not; gave her brandy, for which I had sent to a neighbor's; she became unconscious again, and continued more or less so for several hours; would rouse when spoken to, but always groan and say, 'I am deathly sick.' Pulse remained the same; respiration slow and rather heavy; did not notice pupils.

"Woman, farmer's wife, æt. 68; black hair; goitre of neck; tumultuous and irregular action of heart. Seven and a half grains gave sleep for two hours. Awoke with a scream; jumped out of bed; sat on edge; semi-conscious. Recovery in five minutes; asleep again for two hours; awoke with much epigastric pain. Liebreich's chloral in both cases."*

A letter from Dr. C. F. Rodgers, of ——, possibly bears out the warning given by Dr. Habershon. Chloral is one of those drugs that kill by either heart or respiration, and hence the drug, if given in diseases that tend to kill by the heart or lungs, may work considerable damage by giving impetus to the disease-tendency.†

I have seen two cases of pneumonia that would probably have recovered, in which chloral was used to procure sleep and control delirium. It did neither, but, if possible, augmented the trouble. I will never give hydrate of chloral in any inflammatory trouble hereafter: it will not do. I will only describe one case as a type of both:

A. B., aged 19, inflammation of right lung. Saw him in twelve hours after the attack. Pulse 115, full and hard; temperature 103; respiration 40; skin hot and dry; expectorating profusely. Prescribed, to relieve pain, a mustard-plaster; gave verat. vir., gtt. vi, every three hours; also pulv. Dov. and pot. nit., gr. x every three hours. By the second day he was much better, and I proposed to leave treatment and dismiss in a couple of days. At night he was in the following condition: Pulse 80, soft; respiration 28; countenance natural; decubitus right side; temperature 101; bowels had moved. I gave, to procure sleep that night, hydrate chloral, gr. xx, in two doses, as I did not wish to give any more Dover's powder. I saw him next morning. Had not slept much, was slightly delirious, and from this onward all the symptoms were aggravated, and he died three days afterwards. Tongue clean and moist after the second day to close of disease.

Dr. F. C. Shattuck, of Boston, whose opinion has already been given, agrees with Dr. Liebreich as to the fact that chloral aggravates the excitement of hysteria. Others, however, have used it in these affections with good results.‡ It has been used with good results in hysteria by S. T. Hubbard§ (three cases), James Donaldson,‖ London, England, and R. E. Sutton,¶ Rome, N.Y. James Perrigo,** of Montreal, has found it of advantage in hysterical epilepsy. J. R. Sample,†† of Summit, Miss., says that it is unsatisfactory, and D. N. Kinsman, of Columbus, Ohio, that it is uncertain.

As to its danger in icterus, I know nothing; none of my correspondents speak of it, and I have been unable to find anything in the literature of the subject upon it.

Dr. C. H. Hughes, of St. Louis, Mo., cautions against the constant use of small doses.

I have seen much mischief done by the constant and persistent saturation of the blood with chloral. If a patient has taken chloral in five- or ten-grain doses every hour or two, in a case of high cerebral excitement, for ten or more hours, and has not been sent to sleep for an interval of several hours by this plan, I would consider it dangerous to give a full dose of forty to fifty or sixty grains before an elapsed interval of from eight to twelve hours for elimination of the previous ineffectual doses, which have poisoned the blood and irritated and exhausted rather than tranquillized and recuperated the cerebral centres, whereas a single dose of forty to sixty grains, according to the intensity of the excitement, may be given with impunity when there has been no previous ineffectual action of the drug.

THE USE OF CHLOROFORM AFTER CHLORAL.

M. Fornet,‡‡ of Brest, basing his theory on the facts discovered by Claude Bernard regarding the prolongation or reproduction of chloroform narcosis by means of a dose of morphia, thought it would be of advantage to use another narcotic, giving it, however, *before* the chloroform. The

‖ By letter. ¶ Ibid. ** Ibid. †† Ibid.

‡‡ Bull. Gén. de Thérap., vol. lxxxvii. p. 516.

drug he used was chloral, and, instead of giving it subcutaneously, he administered it by the mouth. He tried it in several cases successfully. In a little girl he produced sleep with a dose of thirty grains of chloral, and then caused her to inhale some chloroform. Complete anæsthesia resulted, and he was able to explore the bladder freely and satisfactorily.

The quantity of chloroform necessary is only from two to six grammes (about thirty to ninety grains).

The use of chloroform after chloral had been taken was, however, found to be very dangerous by Dolbeau.* In three cases, where the patients had previously taken chloral, chloroform produced decided symptoms of collapse, or a very strong desire to sleep, accompanied by great coldness of the surface and weak action of the heart.

One of the cases was that of a lady suffering from fissure of the anus; and it is to be borne in mind that M. Nicaise† claims that the "intolerant fissure" of Prof. Gosselin is generally accompanied by a well-marked condition of the nervous system that renders its subjects highly susceptible to the action of chloroform. Take the following for example. A lady of very nervous temperament, and pregnant two months, being the subject of the "intolerant fissure," was put under chloroform, and soon fell into a state of resolution without prior excitement. After dilatation had been practised, the patient was found to remain still in an alarming state of resolution, the thorax being quite immovable and the pulse very feeble. The various efforts at restoration had to be continued for three-quarters of an hour before respiration could be completely re-established. Vomiting was frequent. Although the quantity of chloroform used was very small, the patient was very near dying. To another nervous woman, forty years of age, chloroform was most carefully given, and after four or five inspirations she fell into a state of resolution without prior excitement. Dilatation was at once performed, and the patient came to almost directly,—the whole having lasted but a moment. Had the chloroform been continued, disastrous results might have ensued. In the case of a man aged 20, a few inspirations produced anæsthesia and resolution.

In other cases the subjects of fissure, M. Nicaise has not met with this excessive sensibility to the action of chloroform; but its possibility indicates the necessity of precaution. The depressing effect of the chloroform was most marked in the first of these cases, the slow form of death which seemed imminent differing from that commonly observed, in which life ceases suddenly and unexpectedly by syncope, the two forms being distinguished by M. Perrin as the adynamic and the conclusive. Other cases in which dangerous symptoms after chloroform have occurred, in the practice of M. Guyon (detailed, as well as those of M. Nicaise, in a recently published thesis by M. Ducamp), have comported themselves differently, there having been a prolonged stage of excitement, and the amount of chloroform consumed being much more considerable. Although none of his cases have proved fatal, they have been sufficiently alarming to lead M. Guyon to perform dilatation without chloroform, making it more instantaneous than by Maisonneuve's procedure, which, while rapid, is still progressive. M. Nicaise does not think that chloroform need be renounced in these cases, but that the surgeon should most carefully watch the phenomena produced while administering it himself, and proceeding to the operation the instant that resolution is produced.

In one of Dolbeau's cases, that of a gentleman with "a painful disease of the rectum," death followed this procedure. In the other two a fatal result was feared, but happily did not occur.

Guyon‡ had a case that nearly proved fatal from the same cause.

Demarquay§ has seen the same symptoms from chloroform alone in a weak, anæmic woman; also in another case. He seems to think that if both agents had been given death would have occurred, and he heartily condemns the procedure.

Perrin states‖ that he has given chloroform after chloral, and the patient recovered, after the performance of an operation, without any bad symptoms.

This method was proposed by M. Fornet for the purpose of lessening the danger following the use of chloroform alone. He seems to think that the danger is in

* Gazette des Hôpitaux, 1874, p. 1165.
† (Gazette Méd., March 18, 1876) Med. Times and Gaz., April 1, 1876.
‡ Gazette des Hôpitaux, 1874, p. 1164.
§ Ibid.
‖ Ibid., p. 1167.

direct ratio to the amount of chloroform used. This we know, from many recorded instances, is not the case, the first few inhalations causing death. Even if M. Fornet was right in this matter, the fact still stands that the method by chloroform and chloral is in itself very dangerous.

Dr. Chas. K. Mills,* of Philadelphia, says that where there is an idiosyncrasy with reference to the action of morphia, a previous dose of chloral does away with all bad effects; and Dr. H. M. Bannister,† of Chicago, Ill., says that he has found it to diminish the stage of excitement in etherization. He says, however, that he has not had much experience in this matter.

ON SOME POINTS IN MEDICAL ETHICS.

Read before the Philadelphia County Medical Society, November 10, 1880,

BY JOHN H. PACKARD, M.D.

MR. PRESIDENT AND GENTLEMEN,—An impression prevails in the minds of the public that there is among physicians a system of imperative but arbitrary and unreasonable punctilio, leading them, as I have repeatedly heard it phrased, to "let a patient die while they are arguing about a matter of etiquette." And even among members of the profession there is apt to be a somewhat mistaken feeling in regard to this subject. They too often have an idea that the Code of Ethics is a set of rules: they have a general desire to act up to it, but a certain indefiniteness as to what the rules are and what is their authority. In the belief that discussion of the subject may be useful, I venture to bring it forward this evening in a few somewhat desultory remarks upon certain points.

Let it be clearly stated, in the first place, that this code is *not* a mere set of rules as to what we may or may not do. Lord Castlereagh is reported to have said that he could drive a coach-and-six through any act of Parliament that could be framed. No law can be established that shall directly meet all the infinite varieties and combinations of circumstances which make up our daily life,—none that can control a body of men like the medical profession, and keep them harmonious, unless it is sustained on their part by the prevalence among them of a high moral tone. Yet, if there is such a tone, and a cordial desire to do right, if the prevailing sentiment is on the side of honor, there is scarcely any need of a law, scarcely any risk of its being transgressed.

Now, when we ask what the Code of Ethics *is*, we shall find it to be simply an endeavor to set forth the relations of physicians with one another and with the public, and to give, somewhat in the concrete, the results of experience upon the general principle which underlies the whole matter.

This general principle is a law through which not even a gnat can creep. No situation can arise in which it is not a safe and adequate guide. It is the simple rule given by the founder of Christianity,—to do to others as we would that they should do to us. Interpreted by common sense, we shall find that this meets all the necessities of every case.

And here let me admit that our Code of Ethics is to me very unsatisfactory. It is so because it does not anywhere give a clear and distinct statement of its fundamental principle; because it is sometimes in the highest degree vague and general, sometimes exactly the reverse. Moreover, as I shall presently try to show, it does not, especially in some of its more concrete directions, accord with the conditions and customs of professional life at the present day.

Professional ethics may be as completely violated by a shrug of the shoulders, by a raising of the eyebrows, or by an inflection of the voice, as by the most flagrant quackery. Against such offences the code itself is powerless, while the observance of its principle would effectually preclude them. A few instances only can be discussed in this paper, but they will serve to show the correctness of the ground now taken.

I have heard the question raised whether a physician had the right to send his prescriptions to a particular drug-store, and an argument of some length held upon it. I have heard bitter complaint made because medicine was ordered by numbers understood only by one druggist. Now let us look into this matter a little.

My business runs in a special direction,—suppose in that of eye surgery or skin diseases,—or I have confidence in a certain

* Phila. Med. and Surg. Reporter, November 9, 1878.
† By letter.

article which, in my opinion, requires a particular method of preparation. Frequently prescribing this, I choose to be sure that my patients get what I order. Now, either for this reason or to save my own time, I arrange with a druggist that No. 1 means such a combination, No. 2 another, and so on. A patient comes to me to ask for advice about himself. What is my prescription? It is simply a formula by which he shall be enabled to get what will suit his present condition. He has no right in it for indefinite use. I cannot be held answerable if, for instance, having a mercurial ordered for him, he goes on renewing and taking it until he is salivated. He has no right to give it to other people whom he may suppose to be affected as he is or was. If I choose to send him to a certain drug-store to get what he needs, I have a right to signify, in any convenient way, what he is to have dispensed to him. For the suitableness of that article to the relief of his condition at the time it is prescribed, and for that alone, I am responsible.

All this is, it seems to me, simple common sense. If now a brother physician asks me for the formula of my prescription, and I refuse to give it, or if I arrange with the druggist to whom my patient must go that he shall pay me a percentage on his receipts for my prescriptions, it is equally common sense that I am infringing the rights of others, and violating the great principle of the Code of Ethics.

Let us now consider another matter. If a physician is called to see a patient in an emergency which has arisen in the course of a sickness, it is clearly his duty to ask who is in attendance upon the case, and to desire that he should be immediately notified. Circumstances must decide whether the first named should simply do what is needful and retire, or await the arrival of the attending physician.

But suppose the case is one of sudden sickness, or of accident. Now, while it would be much better for the physician who is called in to ask who is the family physician, it is not absolutely obligatory upon him to do so. The family physician, indeed, is in a great measure an institution of the past, at least in large cities. There are cases in which it is well known to the practitioner who is thus summoned that the family have usually employed a certain doctor, and then it would be the right thing for the former to ask to have the latter notified. Indeed, it would be not only the right thing, but, to take a lower view of the matter, it would be better policy.

Should the family mention that they have considered Dr. So-and-so their regular attendant, it ought by all means to be regarded as an intimation that he should be notified. Or if, as is often the case, different members of the family have each their physician, it is better to avoid all semblance of interference. And any hint of want of esteem for or confidence in his fellow-practitioner, on the part of the doctor who is brought in on an emergency, is clearly a violation of the great rule.

If the family distinctly request the physician who is thus called in to take charge of the case (where there has not been previous attendance), he has a perfect right to do so; but if he is aware that the family or the patient had within no long time been under the habitual care of another, it would be both courteous and friendly to seek an understanding in the matter with the former attendant. I have known bad feeling to be prevented by this course in more than one instance.

Now, let us suppose that the physician called on in a serious emergency is informed that the attendant is a homœopath. There are too many among us who hold—to parody a well-known phrase—that a homœopath has no rights that a regular physician is bound to respect. We cannot consult with homœopaths, for, if they are honest in their faith, we have no common ground of discussion with them. But we should remember that they have the right to be considered honest in their convictions, in the absence of proof to the contrary. And it should be further remembered that the patient has rights to be respected. Equally, also, we owe it to ourselves and to our profession to show an example of right feeling and of true dignity. Hence I should say that, under the circumstances supposed, the physician should institute such measures as he deems proper, just as if the attendant were of his own school, without raising any argument with the family or friends. If they decline or criticise his aid, he, of course, merely retires. If circumstances demand his remaining until the arrival of the physician, I should say it would be proper for him simply to state what had been the condition of things on his being summoned,

what his view of the case was, and what course he had pursued, and then courteously but firmly to decline any further consultation. This, I submit, would be doing right; and, no matter what might be afterwards said (and unfortunately such things are not always either properly managed or correctly reported), the physician would, I think, have that greatest of all comforts, the approval of his own conscience.

Next, as to the matter of consultations. These, says the Code of Ethics, "should be promoted in difficult or protracted cases, as they give rise to confidence, energy, and more enlarged views in practice." This seems to me to be one of those glittering generalities which tend simply to lessen the authority of the code. Consultations, I think, should be avoided, unless they are really to be of service to the special case in hand. They involve an expense which many families can ill afford; they require the appointment of a fixed hour for the visit, and almost always occupy extra time. Still, if the physician feels the need of counsel, or wants responsibility shared, it is eminently proper for him to call for the advice and help of his brethren. What I object to is the idea that they are always desirable. And of one point I am sure: that the physician in attendance should be allowed to exercise his own discretion in the matter. He may think it proper to strengthen his own position; but if he feels that the family have not confidence in him, and he knows himself to be fully competent, it is sometimes a better plan for him to retire from the case rather than be forced to call a needless consultation.

It is often said that the consulting physician should never supersede the attendant or allow himself to be called in, except in his original capacity as an associate. But if the family designate him, and they afterwards want to employ him, he has a perfect right to respond to the call without any offence being taken by the former attendant. If, however, the latter selects the consultant, and introduces him to the family or patient, the case is quite changed. A physician so introduced should decline to have anything to do with the case, or to attend in the family afterwards, except in consultation with his introducer, unless the latter signifies his full and free consent. The reasons for this distinction, which is also to be drawn in the case of a substitute, seem to me to be too clear to require any argument.

The question is sometimes raised, Suppose there is, in a consultation, a difference of opinion as to important points, are all the physicians concerned bound to assume a position of consent before the family, or, it may be, before the public? This seems at first sight to be a difficult matter to settle; but let us apply our touchstone.

Differences of opinion will arise which cannot be reconciled; each man has a right to sustain his own view, so far as his honest convictions go. But if one party yields, and the result as announced to the patient and family is given as the decision of the conclave, then it should be loyally adhered to by every one of those concerned. If one out of five consultants entertains an opinion irreconcilable with that of the other four and upholds it among them, he has a right to do so anywhere; he is not bound to submit to a majority and smother his own convictions, nor is he bound to accept responsibility for a course from which he has declared his dissent. Propriety and good feeling would forbid his going about and exulting in the independence of his views, but self-respect would compel him to assert them on suitable occasion.

Before quitting the subject of consultations, there is one point which I wish to dwell upon, as experience has shown me its importance. A consultation having been held, the family or friends of the patient are often desirous of getting a private opinion from the consultant. Now, the supposition is that the regular attendant will communicate the opinion arrived at to those who are entitled to hear it, and that he will do so as fully and honestly as possible. I have known much dissatisfaction and want of confidence to result from an apparent discrepancy between the views thus expressed by the two parties, and on one occasion the consultant gave an opinion directly opposed to that he had formerly concurred in, probably because the impression on his mind had become confused and erroneous from the lapse of time and the intervention of other cases.

I would urge, therefore,—although indeed this matter may be thought to belong rather more to etiquette than to ethics,—that all communication with a patient or his family in regard to the case should be through the attending physician, or at

least in his presence; that the consultant should not permit himself to be "pumped," or drawn into anything like heedless gossip on the subject, which may do much harm.

And here I must say a few words as to our modern friends, the specialists. The time has been, not twenty years ago, when a formal report was made to the American Medical Association condemning the practice of specialties *in toto*. This prejudice was based upon what we now regard, and I think with justice, as narrow and partial views. Provided there is a liberal and comprehensive education in medicine, the devotion of special study to certain branches is clearly a benefit to the profession and to the public. And indeed the field of medical literature, the activity of research in modern times, is so vastly greater than in former days, that the man who would keep up with the advances made in all departments would have no time to put the knowledge he gained into practical use.

But it should be remembered by those who thus give themselves to the pursuit of certain branches of practice, that they have still to maintain their loyalty to the great body of the profession. If the oculist or the surgeon avails himself of his acknowledged ability in his own specialty to decoy away the patients who are sent to him by others less skilled in that department, he will find that the slight temporary advantage he thus gains will result in ultimate and far greater loss. The same rules should be held to apply to him, and should be faithfully observed by him, as are obeyed by the profession at large. A surgeon called in to attend a gunshot-wound, or to excise a tumor, should confine himself to his function; and if a member of that family comes to him and says (for instance), "Doctor, we were so pleased with your attention and skill in my father's case that I thought you would be able to cure my dyspepsia," he should remember what is due to his profession and to himself. Loyalty to his brother practitioner will tell him just what to do.

Then there are many cases in which, with the occasional assistance of a specialist, the general practitioner can conduct the treatment with ample ability. Here—and I speak from actual observation—there is sometimes an insidious assumption of superior skill and knowledge, a hinting at the necessity of very special qualifications, which borders far too closely upon what would be recognized at once as quackery.

A few words upon the distinction between *medical ethics* and *medical etiquette*. The former must always stand, so long as the practice of medicine is anything more than a mere business; the latter, in accordance with the prevailing fashion of the day, has nearly disappeared with the wigs, the black suits, and the gold-headed canes which constituted the regalia of our forefathers in the profession.

It would be idle to trace the process of this disappearance. But there is no longer the solemn order observed of entrance into and exit from the sick-room. Seldom indeed does it happen in private practice that more than two physicians meet in consultation. No longer does the array of learned members of the faculty, each in his turn, deliver himself of his opinion. The chance is that the discussion begins in presence of the patient, and that some one, bolder and more outspoken than the rest, does most of the talking, to which the others merely give their assent.

Equally idle would it be to ask whether this is a loss. We cannot return to the old way. It would be at variance with the whole spirit of the social life of the day. It suited the former time, but it would not suit the men of the present.

The great point is that we should not allow this decadence, if it may be so called, to extend to the weightier matters of the law. Whatever be the standard of manners, whether the starched formality of the gentleman of the old school, or the free and easy familiarity of the nineteenth century in its second half, the controlling principle of professional conduct should be one and the same. And this is true in all the varied relations which we sustain among ourselves, to our patients separately, and with the public at large.

The great reason of our existence as a profession is that there is human suffering to be relieved. Wherever this may be found, physicians are ready to go and to act,—as ready now as they were in any former time. Nay, more, we recognize now in a fuller and higher degree than did our predecessors, that our duty is not only that of curing the ills that flesh is heir to, but of preventing them by the study and correction of their causes.

Giving, as we do, the best years of our

lives to the work of preparing ourselves for the accomplishment of these high aims, we render a service to mankind, for which it is but just that we should be paid,—a great service, for which it is but just that we should be well paid. Hence there is between us and the public, between each physician and those under his care, a business relation; but it behooves us to look well to it that we keep this in its proper and subordinate place. If we are to maintain the high social esteem in which, in this country at least, we stand, it will not be by reason of our indispensableness, the vastness of our knowledge, or the cost of our services; it will be because there is plainly traceable in all our conduct in every relation the influence of a pure and lofty principle, founded upon an unalterable basis. What that basis is, it has been my earnest endeavor to set forth in these desultory remarks.

In concluding, I would offer two suggestions: first, that the Code of Ethics might well undergo some revision, to adapt it to the changed order of things and to make it a more efficient guide for professional conduct; secondly, that it would be an excellent thing to explain this subject to students before graduation, so that they might not assume the duties and responsibilities of practice without some definite idea as to their own rights and the rights of others.

THE INJURIOUS EFFECTS OF THE CONSTANT USE OF BABY-CARRIAGES AND BICYCLES ON THE PHYSICAL DEVELOPMENT OF THE YOUNG.

Read before the Philadelphia County Medical Society, November 10, 1880,

BY HENRY H. SMITH, M.D.

AS the natural attitude assumed by man is that which is most favorable to his locomotion, and as this, contrary to the locomotion of animals, is the erect or vertical position, he holds it, in the exercise of walking, by such muscular efforts as preserve his equilibrium. To accomplish this, he is endowed by nature with two grand classes of muscles (flexors and extensors), each of which, in the state of nature, is capable of antagonizing the other, so as to resist the force of gravity, or the inclination of all bodies to be drawn towards the earth's centre.

In standing, this line of gravity falls perpendicularly on the base that sustains the body, or upon the feet. In sitting, the base of support is the pelvis, the centre of gravity being found between the pubis and the sacrum, the vertebral column being also so arranged by a series of antero-posterior curvatures as to maintain this vertical line through the shape of the various pieces of the column, aided by the varying thickness of the intervertebral cartilages as well as by the posterior and anterior vertebral ligaments. These structures, offering only a partial resistance (as may be shown by attempting, in a ligamentous preparation, to keep the head and spinal column in a vertical position), are greatly aided, indeed, mostly sustained, by the muscles found on the back and front of the column, and especially by such as are connected also with the pelvis; such as the sacro-lumbalis and longissimus dorsi, aided by the spinalis dorsi; or the entire set of muscles sometimes described as the erector spinæ.

In addition to these powerful erector muscles, we find the semi-spinalis dorsi and the multifidus spinæ participating in preserving the equilibrium of the trunk; whilst, from some of the connections of many of them with the ribs, an influence is exercised by their action on respiration and thoracic development.

As the power of every muscle is increased by its exercise, it is an important point in the physical development of children that this fact (muscular action in the erect posture) should be impressed by the physician upon the minds of all who control or direct their physical education, especially in infancy.

Ordinarily, infants preserve two attitudes, one passive, the other active, the latter chiefly contributing to their proper growth. When a child lies down, as it usually does in a baby-carriage *during infancy*, it reposes upon an extended base, and, as the force of gravity is barely felt by it, the muscles of the spine remain nearly at rest. When a child sits up, most of its spinal erector muscles are in action, though varying in intensity. The vertical position, or that in which an infant sits upon its nurse's arm when carried, necessitates a balancing of the head and upper extremities upon the infant's pelvis; with alternate action of the erector spinæ muscles and those of the abdomen that flex the spine by bringing the thorax towards

the pelvis; as well as of those which cause a bending sideways or give the lateral motion to the body, as the quadratus lumborum and psoas magnus muscles. Hence, when a child is carried on the arm, its exercise in preserving its balance or equilibrium prepares its muscles for the more steady action demanded of them subsequently in creeping; or, more especially, in walking.

A child that is carried is therefore being constantly educated or trained in balancing its head and shoulders; whilst the abdominal muscles, which here act as flexors of the spine, also compress the liver and other abdominal viscera and aid the peristaltic action of the bowels, as well as the action of respiration. In addition to this, such infants are sooner able to sit alone, and creep or walk more vigorously, than those who in the continued supine posture of the baby-carriage fail to receive this muscular exercise. With the increased expansion and contraction of the thorax there is also improved respiration and oxygenation of the blood-corpuscles; whilst the waste of tissue that ensues on muscular action creates increased necessity for repair, and we therefore have increased appetite, with improved digestion and nutrition.

The advocates of the use of baby-carriages contend that they are beneficial by keeping an infant longer in the fresh air than can be done when it is carried by a nurse, who soon becomes fatigued.

This is certainly not true in many instances, as a woman who is not strong enough to carry an infant, even if it weighs twenty-five pounds, is physically unfitted for her duty as a nurse. Such an objection is very apt to be raised by the nurses themselves, and should be regarded with suspicion by the mother. Often it is evidence of laziness or a fondness for flirtation or talking, as may be noted at any time in our parks or squares, and especially in Rittenhouse Square, where many nurses of wealthy children can be daily seen amusing themselves by the hour, totally regardless of the infant, who may be likewise seen with its head hanging out over the side of the carriage, so as to compress the veins of the neck and induce a certain degree of congestion of the brain, if it is not found in some equally improper and injurious attitude likely to result in curvature or caries of the spine, the origin or exciting cause of which it is subsequently difficult to recognize.

Another evil liable to ensue from the constant use of the baby-carriage is the jarring and concussion of the delicate brain and spinal cord of the infant, created by bouncing the carriage over gutters or up and down the curbstones of our sidewalks. This evil is quite as serious to the infant as the concussion of the spine alluded to by Mr. Erichsen as the result of railroad-travel, is to the full-grown man; the nervous system of the child being very easily impressed by jars or concussions.

The baby-carriage mania has now reached that point in Philadelphia that an infant and a coach appear to be inseparable, and, though the cost of a baby-carriage is quite an item in the expenses of the nursery, "few there are so poor as not to do it reverence." Of course, it is admitted that there may be instances where the use of a baby-carriage occasionally by a child able to walk a little, or where the carriage permits a poor, tired mother to obtain for herself a little relaxation whilst keeping her baby in its carriage in the Park, or in the case of feeble children or those recuperating from an attack of illness, is advantageous; but, as a general rule, the anatomical and physiological facts just alluded to may be deemed as sufficient to induce physicians to give attention to the abuse of a custom that is by no means the result of necessity in the case of infants or those under twelve months of age.

The use of the baby-carriage is also quite a modern fashion, and mainly consequent on a residence in a large city and a so-called fashionable neighborhood. In the country, a baby-carriage is almost unknown, and the infant is much sooner left to take care of itself on the floor and exercise its own muscles. A few years since, a nurse who was asked to drag or push a baby-carriage would refuse to do so, saying, "Does the likes of yez think I am going to make a horse of meself?" Now, they complain of being expected to *carry* a baby.

In support of these views—viz., the evils liable to result from the continued use of the baby-carriage by infants—I have noted the following facts:

An infant now nine months old has never been allowed to enter a baby carriage, but has taken its exercise out-of-

doors, for several hours at a time, on its nurse's arms. It is now (nine months) able to sit alone; creeps around actively; seldom falls or bumps its head; is bright and observant of everything; creeping to obtain any article that attracts its notice. It has a bright color, nurses and sleeps well, and has had no trouble in teething, its digestion being perfect.

Another child, much larger, and weighing twenty-seven pounds, has been kept constantly in its carriage, this being regarded as an excellent place for it to sleep in during the day. It is at present entirely unable to sit erect, even when aided by pillows; has a feeble digestion, suffering constantly from flatulent colic, and is altogether much more passive in its physical and mental habits than the other child. Both have been suckled.

The question seems, therefore, to be worthy of investigation,—"Whether the constant use of the baby-carriage is not entailing serious injury on infants or those within the year?"—and I have thought it deserving of the notice of the Society.

Some years since, the "baby-jumper," or a mechanical arrangement by which a child sat astride of a broad band so suspended that its toes could barely touch the ground, was quite the fashion, as it enabled the child to take care of and amuse itself whilst taking exercise by a species of jumping, in which it was aided by the elastic bands from which it was suspended. The development of pes equinus, caused by the constant touching of the earth by the toes as the child strove to obtain its spring, or a change of fashion, soon led to its being given up, so that to many persons it is now a thing unknown.

A somewhat similar deformity is, I fear, likely to be created by the use by young and growing lads of the bicycle, the extreme flexion of the toes to reach the treadle that works the machine causing too much action of the flexors of the toes, as well as of the gastrocnemius and soleus muscles, thus also inducing pes equinus. I will say nothing of the creation of fractures of the radius and other injuries that frequently ensue on falls from the bicycle, as with these all are familiar. If, as is probable, this means of locomotion is with some to supersede the more advantageous exercise of walking, let at least special attention be given to the length of the rider's leg, and let it be seen that the treadle is not so far from the sole of the foot as to necessitate a constant elevation of the heel in order that the toes and ball of the foot can reach the point of progression.

The subjects to which I have thus briefly invited the attention of the Society are some of those which, though of daily observation and seriously affecting the proper development of the young, have not, as far as I know, been discussed professionally. Sanitarians are, however, beginning to note the effects of these injurious fashions upon children. The *Sanitarian*, of New York City, reprints in a recent number an article from the London *Lancet* on "Children's Hats," objecting to the senseless fashion of turning up the brim of the hat in Tyrolese or Spanish fashion, so that "infants and little folks of tender years have half-closed eyelids, corrugated brows, and faces screwed up by the glare of the sunshine, from which the brim of the hat, if correctly used, ought to protect them."

More than one hundred years ago, Addison, in the *Spectator*, said, "The most improper things we commit in the conduct of our lives we are led into by the force of *fashion*,—a prevailing custom making us act against the rules of nature, law, and common sense." The lapse of time, and the enlightening of our people by the increased facilities of education, do not appear to have materially modified the popular folly against which Addison at that time wrote in England, and *fashion*, not common sense, now, as then, appears to sanction many customs that are contrary to the laws of nature.

In calling attention to the violation of these laws by the public, the medical profession exhibits the humanity and benevolence that is its noblest characteristic, and this Society has shown its appreciation of such duties in establishing a special committee "On Hygiene and the Relation of the Profession to the Public," as well as by special investigation of the vision of the thousands of children in our public schools, and other similar measures. To discuss, therefore, the evils liable to result from the fashions alluded to in this brief paper, especially as their continuance is liable to impair the symmetry and corporeal activity of the next generation, cannot be regarded as otherwise than a humanitarian action on our part.

LIQUOR ERGOTÆ PURIFICATUS.

BY F. LESSING, M.D.

AT the meeting held by the College of Physicians, October 13, reported in full in the *Times*, I notice that comparatively little credit is bestowed upon the hypodermic use of ergot in hemorrhage incident to parturition. I have had, this summer, two terrific "bleeders," and I assure the profession that the above preparation saved my patients, although the hot injections were used freely.

I cannot recommend the above too highly. It is manufactured by Park, Davis & Co., of Detroit, Michigan; does not create inflammation or abscess; can therefore be used with impunity. In the cases mentioned above I did not count drops, but simply filled my syringe, injecting as near to the uterus as possible.

Again, I may be at liberty to mention the position of those bleeders, which was seemingly very little discussed. I am in the habit of not only elevating the podex well, but also of having their thighs well flexed, so as to give the uterus full *play*-room for contraction. How the Crédé method can be so much recommended remains a mystery to me, for heretofore I have not come across a patient who could stand the smallest pressure or manipulation of the uterus without shrieking with pain.

WINONA, MINN., December 21, 1880.

"CRÉDÉ'S METHOD."

BY JOHN W. SNOWDEN, M.D.,

Waterford Works, N.J.

AT the meeting of the Philadelphia County Medical Society held October 13, during the discussion on a paper entitled "Hemorrhage incident to Parturition," Professor Goodell, in allusion to Crédé's method of delivering the placenta, said he did not believe this plan had ever been practised by Dr. Atlee or by any one else before it was devised and recommended by Crédé,—at least, such a plan had never been described or published by any other physician.

I know that Dr. Warrington taught this method in 1843 and 1844, as I was a pupil in his "Obstetric Institute" for one year, and was his assistant for a short time before I left Philadelphia.

I have heard him make use of the very same expression as Professor Goodell. He would tell his class to "grasp the uterus in such a way as to squeeze the placenta out, as you would force the stone out of a cherry."

TRANSLATIONS.

DORSAL DISEASE OF THE TOES.—Prof. Dubreuil (*Gaz. Méd. de Paris; La France Méd.*, 1880, p. 673) recently delivered a lecture on the affection to which he has given this name. It begins by the formation and inflammation of a serous sac abnormally developed beneath a bunion which has developed on the dorsal surface of certain toes, ordinarily near the articulation of the first and second phalanges. When no deviation of the toe has taken place, the serous sac does not usually become inflamed, but if the toe is crooked, especially if the apex of the angle formed by the first two phalanges is upward, so that it is exposed to friction and pressure, inflammation takes place and runs through its various stages. The ordinary corn is an accumulation of epithelial cells which penetrate by a sort of root into the derma. In the bunion, on the other hand, epithelial cells are found in the upper part, while lower is the rete Malpighi intact, and lower still a papillar hypertrophy, frequently very marked. Finally, below the derma is a serous sac, situated immediately upon the extensor tendon. Many persons carry a bunion for years in an indolent condition. Some unusual exposure, as in a forced march, may cause inflammation of the serous sac. Effusion takes place, and an abscess forms, which appears on the dorsal surface of the toe. This opens and terminates in a fistula, from which issues a sanious fluid. Whenever the individual takes a long walk this toe becomes tumefied, red, and painful. Rest brings relief. If neglected, the inflammation finally penetrates to the articulation and destroys the cartilage. The prognosis then becomes grave, and disarticulation or amputation may have to be resorted to. As to treatment, when the tumor is indolent the toe should be straightened if in a vicious crook. Inflammation of the sac is to be combated with emollients. Where pus has formed, it must be given vent, and the fistula scarified or cauterized with nitrate of silver to

the bottom of the cavity. If the articular surfaces are involved, disarticulation, or, better, amputation in the continuity of the first phalanx, should be performed.

Physiological Action of Conium Maculatum. — At a recent meeting of the Académie des Sciences (*Bull. Gén. de Thérap.*, 1880, p. 365) M. Bouchefontaine alluded to the fact that in 1878 he had, in collaboration with M. Tiryakian, presented a paper on conium maculatum which went to show that hemlock owes its properties to two active constituents,—one, conine or cicutine, paralyzing the central nervous system, the other acting like curara. In 1879 M. Prévost, of Geneva, presented a note to the Academy, in which he considered the bromhydrate of cicutine as a paralyzant of the motor nerves.

Bouchefontaine, by recent experiments, has satisfied himself that conine diminishes or abolishes the physiological properties of the nervous centres before acting, like curara, on the nervo-muscular cement-substance (*substance jonctive*). On the dog and frog this alkaloid always ends by abolishing the nervous excito-mobility if it is given in sufficient quantity, but it is then fatal to batrachians and mammifers. Its action is therefore different from that of curara. The effects of the bromhydrates extracted from hemlock in a crystallized condition are as follows:

They are to be divided into two groups. One is composed of amber-colored crystals, is more toxic than the other, acts like conine, and represents the most active principle of hemlock. The other variety of crystals, which are less poisonous, are colorless or of a pearly lustre, and resemble those obtained by Prévost. They act differently, however. As to the comparative action of hemlock and curara, this may be formulated thus: hemlock may act like curara, but it produces, in addition, certain physiological effects not observed in animals to whom curara has been administered.

Action of Collodion on the Temperature.—Raducasi, in his thesis (*Bull. Gén. de Thérap*, 1880, vol. xcix. p. 380), comes to the following conclusions. 1. The application of flexible collodion on the central temperature in the physiological condition is variable according to the locality covered. 2. Applications made to the limbs have no influence on the central temperature. 3. If the application is made over the entire cutaneous surface corresponding to the peritoneum or to the pleuræ, an immediate lowering of the central temperature takes place. 4. The comparison of the action of the application made on a cutaneous surface corresponding to a serous membrane with that produced on a cutaneous surface corresponding with masses of muscular tissue may perhaps explain the therapeutic action of collodion in inflammation. 5. The action of collodion on phlegmasiæ, whatever its nature, is beyond question.

Fracture of the Humerus dependent upon Muscular Contraction without Previous Disease of the Bone. — E. Belajew (*Cbl. f. Chir.*, 1880, p. 720; from a Russian source), having had his attention attracted to Foster's case (see *Medical Times*, No. 334, 1880), reports the case of a school-boy of 15, in whom fracture of the junction of the middle and upper thirds of the humerus had taken place, with slight lateral dislocation of the fragments. The patient enjoyed perfect health, without a trace of rachitis or osteomalacia. He had been playing with his comrades, when, on throwing a metal plate of about a pound weight with all his force, he suddenly felt a cracking in the right shoulder, with severe pain, the arm falling helpless by his side. Under appropriate treatment the fracture united within five weeks.

Medicinal Uses of Indian Hemp.—Dr. Michel (*Montpellier Méd.; Bull. Gén. de Thérap.*, 1880, p. 380) again calls attention to the value of Indian hemp, particularly in the treatment of uterine affections. He proposes the following formula in metrorrhagia:

℞ Tincturæ cannabis indicæ, ʒss;
Syrupi simplicis, fʒj;
Aquæ ad fʒviij.—M.

Sig.—A teaspoonful every five or six hours.

His experience leads to the following conclusions. 1. The action of Indian hemp is double,—excitant in small doses, in larger ones sedative and even hypnotic. 2. Of use in most nervous affections, it is particularly valuable in chorea, tetanus, certain cases of mental alienation, delirium tremens, and neuralgia. 3. The muscular tissue of the uterus is particularly sensitive to its influence; metrorrhagia is stopped by it, and the uterine contractions so increased that it might be substituted for ergot.

Local Anæsthesia by Bromide of Ethyl.—Terrillon (*Bull. Gén. de Thérap.*, tome xcviii. No. 7) prefers this anæsthetic to ether for local use, (1) because it can be used without danger after dark, being non-inflammable; (2) it has a very slight odor; (3) less is needed than when ether is used; (4) the wound is not irritated, and the pain after anæsthetization is less marked; (5) no ice-crust forms on the frozen spot; (6) the thermo-cautery can be used with ease in bromide-of-ethyl spray.

The tissues become frozen after two to three minutes. By the thermometer, the temperature falls at the same time to 15°. Bromide of ethyl has a specific gravity of 1.40, boils at 40.7° C. (105.2° F.), is easy to prepare, and very stable. Terrillon has used it in numerous cases with the best results.

Poisoning by the Seeds of the Ricinus Communis.—M. Lugeol (*Bord. Méd.; Bull. Gén. de Thérap.*, 1880, p. 431) calls attention to the danger of poisoning by the seeds of the ricinus. These, he says, are of an agreeable taste. A woman took, at three o'clock in the afternoon, six seeds. In the middle of the night she was awakened by vomiting, with violent colic, accompanied by choleric diarrhœa. The symptoms were exactly those of an attack of cholera morbus,—eyes sunken, pulse feeble, cold skin, muscular cramps, with extreme pain. The patient was given alcohol and acetate of ammonia, while hot applications were made externally. She recovered.

Menstruation at Seven Months.—Dr. Cortejarena (*El Siglo Médico; Le Réveil Médical*, 1880, p. 202) reports the case of a child who menstruated regularly at seven months. At twenty-eight months it seemed, by its rounded figure and turgescent mammæ,—as large as citrons,—its well-developed vulva and clitoris, to resemble a little woman. There was nothing in the mental or moral development of the child corresponding to this precocious physical evolution.

Phosphate of Bismuth as a Substitute for the Subnitrate.—Dr. Tedenat (*Union Pharmaceutique*) prefers the phosphate of bismuth to the subnitrate. The anti-diarrhœic effect of the phosphate is exercised in the same manner as that of the subnitrate, but it may be given in smaller doses, one to two grammes (15–30 grains) as a general thing. It is administered in the same way as the subnitrate, either in powder, in suspension, or in pastils.

Nerve-Stretching in Sciatica.—Hildebrandt, in the case of a woman of 32, the victim of sciatica, laid bare the ischiatic nerve in the popliteal space, and stretched it in both directions as far as possible six times. The pain ceased immediately, and did not return. In a second case, where a young man suffered with stiffness in the right finger, with pain, following a thorough wetting, the brachial plexus was stretched, with the result of a perfect cure.

Ointment for the Chronic and Subacute Pains of Gout and Rheumatism.—Dr. Lenoble suggests the following formula: Caoutchouc (finely cut), myrrh, canella, and salicylate of sodium, of each ten grammes (one hundred and sixty grains); sufficient essence of turpentine to bring to a fluid consistence. The joints to be rubbed thrice daily, and covered with raw cotton.

Prolapse of the Vagina in the Virgin.—Dr. Guillermet (*Jour. Méd. de l'Ouest; Le Réveil Médical*, 1880, p. 119) reports the case of a girl of 18 frequently affected with prolapse of the rectum, who, after an invalid infancy, had begun to menstruate at fourteen. One day, after long and severe efforts at defecation, she found a tumor between the thighs, which, on examination, appeared the size of two fists, of a vinous color, large at the bottom and narrow towards the vulva, confined by a constricting ring. A sort of strangulation had taken place, with œdema. In the centre an orifice with radiating folds permitted the introduction of the finger, which, however, failed to find the cervix uteri. The reduction of this tumor was a matter of some difficulty, but was accomplished. A month later the hymen was found intact, its opening in the form of a longitudinal slit. The vulvar ring was firm and tight. No prospect of relapse.

The prolapse of the vagina without involvement of the uterus is very rare. In the case of this young girl it was due to predisposing feebleness of constitution, habitual constipation, and efforts at defecation. In another case quoted, the uterus also was involved. The patient, although a virgin, showed relaxation of the vulvar ring. Cure was effected by excision and suture of a portion of the anterior vaginal wall.

EDITORIAL.

SURGICAL MALPRACTICE-SUITS.

TWO very curious legal cases have recently occurred which threaten to add to the difficulties or perils that already environ the work of the surgeon, and require that attention should be directed to them. The full details of the New York case may be found in the *Medical Record* of December 15, but the essential features can be stated in a few words.

Dr. Noyes was operating upon the right eye of a patient suffering from double cataract, when he found that the pupil was so blocked up by an intraocular membrane or growth that no good would result. Without arousing the man from his anæsthesia, the surgeon then operated upon the left eye, ceasing from his efforts upon the right. The result was bad, and the patient sued, basing his claim for ten thousand dollars damage upon the fact that he had only consented to have his right eye operated upon.

All the lawyers seemed to agree in the opinion that if no consent is given to an operation the surgeon is liable; but the point to be decided was how explicit that consent must be. It is absurd to deny a surgeon the right to modify his operation when he finds unexpected difficulties; but it is also plain that careful men will hereafter get the consent of patients to do what may seem best to be done whilst the operation is going on.

We have not seen the charge of the judge, but the *Record* says,—

"Judge Russell stated in his charge that he could find no records of a similar case; that it was an extraordinary one, in that it brought up the question as to what constituted legal permission,—whether or no there was reasonable ground for the doctor to assume that his proposition was consented to. But the point in law which has perhaps as much importance to the surgeon as any other brought out by his honor is the charge that the patient, under the excitement of an impending operation, was not competent to revoke any authority previously given regarding the character or extent of the operation. The jury disagreed, but brought in a verdict of ten to two in favor of the defendant."

The second case is reported in the *London Medical Times and Gazette* for December 11. In it a servant-girl was suspected by her mistress of being *enceinte*. A medical man was sent for, and the girl examined. She afterwards sued both mistress and doctor for assault and battery. The case was argued several times, elicited antagonistic rulings from different judges, and resulted in a non-suit in favor of the mistress and acquittal by a jury of the doctor. The patient swore she did not consent, but the jury seemingly did not believe her. As one of the judges ruled that "a submission to what was done, obtained through a belief that she was bound to obey her master and mistress, or a consent obtained through fear of evil consequences to arise to herself, induced by her master's or mistress's words or conduct, was not sufficient," explorations of the purity of servant-girls would seem to be even more risky than the practice of medicine.

WE have received from the publisher, Mr. Theodor Fischer, of Cassel, Germany, copies of Dr. Paul Börners Reich's "Medicinal Kalender" for 1880 and 1881, a work of whose existence we must confess to previous ignorance. The first part of these calendars is a pocket-book similar in its scope to an American visiting-list, but of a ponderosity befitting the heavy intellectual and muscular development of sons of the Vaterland. The second volume is that which will most interest foreigners. It is really a complete directory of the physicians of Germany, including such information as usually finds place in our medical directories. The medical faculties receive due notice; the royal family is not slighted; the various local

and general laws regulating the profession are analyzed; schedules of fee-bills abound; medical and scientific societies, with their presidents and secretaries, are tabulated; and the medical *personnel* of the great German army is fully considered. Each book contains such a mint of information that we shall place them in the library of the College of Physicians, where those who desire may find them.

CORRESPONDENCE.

LONDON LETTER.

THE subject of the dispute at Guy's Hospital still occupies the attention of the profession, and any practical solution of it seems still shrouded as much as ever from sight. The senior physician, Dr. Habershon, and the senior surgeon, Mr. Cooper Foster, have resigned their posts, after many long years of service in connection with the institution. What effect this step will have upon the contending parties it is not easy to say. The lay governors show no signs of giving way; the medical staff are "solid;" so what the issue will be will reveal itself in time. It appears that at one time the committee contained several medical men; but how their places were filled up by laymen, instead of by other medical men, probably involves obscure petty politics in the past, and suggests "ways that are dark," if not "tricks that are vain," judged by their outcomes as manifested in the present imbroglio. It is that want of loyalty to their profession manifested by certain members of it which leads to troublesome consequences in time. No doubt in this case certain medical men were kept out of the committee by intrigue, and laymen put in instead, until the medical element ousted itself entirely. They have sown the wind, and we are reaping the whirlwind. And there appear sundry unmistakable evidences that the profession is about to go through a time of trial and probation, and we trust of purgation, until its rightful position is accorded to it; but it must do something to see that it does not so frequently allow men of second-rate ability to get into prominent places where only the very best men in the profession should be found, nor make its selections for wealth, urbanity, or perhaps, sometimes, for capacity for intrigue, instead of sterling merit, in the future. The nursing sisterhoods are apparently determined to make a desperate struggle with the profession for the confidence of the public; and it must be admitted that the profession does not occupy that commanding "position" which its friends could wish to see it hold. Humanity has an impression that above all things doctors should be healers; that when one sends for a medical man one should hope to get some good therefrom. It was all very well for the vanity of Mr. Borthrop Trumbull to be tickled by the examination of his "secretions;" but this brilliant sketch by George Eliot, in "Middlemarch," has brought vividly into prominence the "do-nothing" phase through which medicine has just been passing. Homœopathy fired a volley over the grave of "heroic treatment," and the echo resounded far and wide through the public mind, and only was lost at last in the rejoicings which announced the birth of a phase of "expectant treatment" the essence of which was "to let the patient alone." Doubtless in acute disease an advantage has been gained as regards a large proportion of the profession,—viz., those who act without careful thought,—and the present fashion is less homicidal than the heroic treatment in unskilful hands. But the balance has swung too far in the opposite direction, and medicine has been emasculated to a great extent, and practically stands in its present contest with the energetic sisterhoods like a eunuch fighting an Amazon. However objectionable to some men this simile may be, it does not unfairly represent the condition of the two contestants in the present warfare. Propositions as to what is to be done are plentiful: petition Parliament; invoke the aid of the British Medical Association; enlist the active sympathies of the journals, etc., etc. It is somewhat ominous that the enterprising editor of the *British Medical Journal* maintains his present attitude in the matter.

However, to turn to a more pleasant subject for the thought of a medical man, Dr. Ferrier, F.R.S., recently read a paper before the Harveian Society on "Tumor of the Cerebellum." All are aware how much Dr. Ferrier has contributed to the recent advance in our knowledge of the brain, and our improvement in the diagnosis of cerebral disease from our acquaintance with the functions of various areas; and the diagnosis made in the present case, and borne out by the post-mortem examination, illustrates this famously. A man of middle age first began to feel giddy; this grew more marked, and he began to "heave" to the left side, giving beholders the impression that he was intoxicated. Then came on some dimness of vision, most marked in the left eye. Then came on pain in the occipital region, intensified when he lay on his left side in bed. After that his speech became thick; then followed deafness in the left ear. Such was the order of the head-symptoms. The autopsy revealed a tumor "of the size and shape of a hen's egg, concealing the under surface of the left lobe of the cerebellum, and causing a divergence of the pons Varolii and

medulla in a curve towards the right. On lifting the tumor, the left side of the pons was seen to be hollowed out and compressed towards the right side, and the left middle cerebellar peduncle appeared flattened and drawn out, following the left lobe upwards and backwards. The region pressed on included the roots of the fifth nerve anteriorly. The sixth, slightly displaced, was free from compression, and visible at the inner margin of the tumor. The seventh, eighth, and ninth lay in the centre of the hollow made by the tumor, and were displaced upwards, but there was no solution of continuity of the nerves. The roots of the hypoglossal nerve were flattened against the olivary body and lateral tracts. Situated in the angle formed by the pons, medulla, and flocculus, and concealing the origins of the seventh and eighth nerves, was a small tumor of the size of a cob-nut, which, however, had not caused any evident indentation of the parts on which it lay. The roots of the nerves were distinct. The fifth, sixth, and ninth nerves were entirely out of the region of pressure on this side." Such were the relations of the tumor.

The following are abstracts from the remarks of the doctor upon the case; but, as his work is always condensed to the utmost extent compatible with absolute accuracy of diction, any one wishing to make notes of the case had better consult the paper in the *British Medical Journal* for December 11, 1880. There were some small nodules on the surface of the cerebral hemispheres, but they were "unimportant," diagnostically, compared with the large tumor under the cerebellum, and probably they only appeared late on in the case. Occipital headache is common with cerebellar tumors: percussion over the painful area is diagnostically valuable. The pressure on the nerves gave precision to the diagnosis: thus, taste was abolished only in the anterior two-thirds of the tongue, the region supplied by the gustatory branch of the fifth, while the region of the glosso-pharyngeal still retained its functions. Thus, too, the total deafness of the right ear was a difficulty cleared up by the discovery of the second and smaller tumor. Then the deafness, without corresponding diminution of the function of the portio dura, is to be explained by two matters. 1. The more specialized a function, the more it suffers from lesion of its nerves and nerve-centres. The highly-specialized sense of hearing is abolished before the functions of the facial nerve are perceptibly impaired. Then the portio mollis is more readily compressed than the portio dura, as their names would suggest. Two symptoms specially characteristic of cerebellar disease were well marked in this case,—viz., vertigo and unstable equilibration, both as regards station and locomotion,—or perhaps rather vertigo *with* unstable equilibrium. When found together, these are very suggestive. The eyes being open or shut made no difference in this case over healthy individuals. The matter of "cerebellar reel" is, Dr. Ferrier thinks, of more importance than is generally accredited. The direction of the reel is still less studied, yet in this case it pointed to the disease being in the left lobe of the cerebellum more particularly. The cerebellar lobes are in relation especially with their own side of the body, and regulate the motor adjustments necessary for equilibration more particularly on their own side. It is known experimentally that one cerebral lobe may perform the work usually carried on by two, but in the case of the cerebellum this is not yet ascertained. The general compression of the cerebellum enfeebled the right lobe, and so clouded the symptoms. In the diagnosis of cerebellar disease in its early stages it is well to investigate the matter of equilibration very thoroughly. When the disease is advanced, it may be enough to ask the patient to stand or walk and the impairment is revealed; but in the early stages it is necessary to test the patient by measures which task the powers of equilibration more severely, such as standing first on one leg and then on the other. By such means impairment of the more difficult actions tells of commencing disease, while the more ordinary movements can still be performed so well as to create no suspicion. This tracking down of disease of the contents of the encephalon by means of our knowledge of the functions of different areas is one of the practical outcomes of our experimental inquiries which promise in time to lead to operative procedures for the removal of morbid growths within the skull, while the success of the antiseptic system in the treatment of deliberate injuries to them renders such operative measures perfectly safe as regards their justifiableness from a moral point of view. Rash as such a proceeding would have seemed to such a surgeon as the late William James Syme, whose death is still fresh in the memories of those who were familiar with him—in his swallow-tail, black continuations and waistcoat, with a black or black-and-white silk tie—and his fierce antipathies, and his advocacy of antiseptic surgery against Professor Simpson's acupressure, a few years have worked a wonderful change in these matters. And what betwixt our increasing knowledge of what the brain and its coverings will tolerate if carefully manipulated, and the excellent results of the antiseptic treatment of surgical injuries to it, lately ascertained experimentally by Professors Gerald Yeo and Ferrier, it is not very rash to say that it seems probable enough that in five years tumors within the skull will be diagnostically localized and then removed, with—well, we will see in time with what results.

The peritoneum used to be a terrible bugbear to the surgeons of the past, while the performers of ovariotomy at the present time

scarcely take it into consideration, it has become so tolerant of injury. Indeed, the serous membranes seem to have taken on quite a new attribute—one of forbearance—at present. Rheumatic fever used to hold on week after week, and even month after month, while nowadays it takes itself off almost at the first summons; and if it were not for the practice of getting the patients up too soon, and so keeping up inflammation in the cardiac valves, even the resultant heart-changes would become comparatively rare. Consequently, when growing so pacific in the abdomen and the thorax, there seem grounds for trusting that even in the encephalon the serous membranes will allow surgeons (who treat them with proper deference) to manipulate them upon occasion without too fiercely resenting their procedures.

It is now exactly a year since I was the object of much execration and some correspondence in a prominent medical journal for my remarks upon the social position of the profession and of doctors' wives. In the correspondence it was pointed out by Dr. Norman Kerr, of teetotal notoriety, that the social position of medical men in Scotland and in Ireland was far superior to that accorded to their English brethren; and as this was not called in question, at least by anything which appeared in print, it might be assumed to represent the state of matters fairly. Well, let us see what appears in a leader in the *Medical Press and Circular* for December 8. It appears therefrom that a medical man, a graduate of the University of Edinburgh, once a clinical clerk in the famous Royal Infirmary there, a man who has held several excellent appointments in different parts of Great Britain, a contributor of a number of articles to our leading medical journals, therefore a man who works at his profession, and a man who has held a good social position, and who is presumably a gentleman,—it appears that this medical man, for reasons of his own, settled in the Isle of Skye. Now, this man was a very good specimen of the country practitioner, from his antecedents. The distances to be traversed in the Isle of Skye are great, and the roads are rough and uneven; and the doctor had returned from a twenty-mile journey, when he found a message for him to go to Armadale Castle, seven miles away. He had only one horse, and the brute was so exhausted he could not be taken out again (there is no account given as to whether the man was weary or not). So, as nothing was said as to the case being urgent, the doctor postponed the visit till the next morning, and on arriving at his destination found the case one of toothache in a visitor,—one of the gentler sex. An explanation was tendered, something was prescribed, and on the following visit, made a couple of days later, all was well. Still, the medical gentleman was not invited to enter the house or thanked for his courtesy in making this call.

But the matter did not stop there by any means, and the offence, if offence it could be termed, was punished by very serious measures. A few days later the attempt was successfully made to deprive the doctor of his parochial appointment,—the *pièce de résistance* in a country doctor's bill of fare,—on the ground that he was remiss in the discharge of his duties. A letter asking for some explanation was tendered to the peer at Armadale Castle, couched in the most respectful language, and in answer he was told "that the members of the board were all of one opinion, that he would not do as medical officer for that parish." The doctor's wife then wrote to Lady Macdonald as follows, and the terms of the letter speak for themselves:

"We flitted here scarcely eighteen months ago, and now, greatly through some misunderstanding, we are again on the eve of being compelled to remove out of the situation the duties of which we tried to fulfil to the best of our ability. I appeal to your ladyship's well-known amiability and kindliness of heart to use your influence in our behalf, or at least to let us know how we have merited the withdrawal of your support."

This seemed a very fair and reasonable request, entitled, on its merits, to a courteous reply at least. "Lady Macdonald is very sorry she cannot help Mrs. Jefferiss about her husband's dismissal." This was the answer of the peeress to the country doctor's wife!

The next insult offered to the doctor was that of abridging the period which ought to elapse before his appointment should expire after his resignation. This is a device which is agreeable to some minds; and it is within my personal knowledge that a member of a committee of a public institution could get access to the check (signed but not filled up, in order to allow of the outgoing medical man arranging with his successor) and on his own responsibility fill it up; so that if the outgoing man remained any longer at his post he would work for nothing or have ten times more bother to get any recompense than the sum would be worth. This form of insult recommends itself to some minds.

Then followed a very substantial injury. The factor of the incensed peer wrote to the doctor as follows:

"I have to intimate to you that the subscription which you have hitherto been receiving from Lord Macdonald as medical attendant at Armadale will now cease. I have also to intimate to you that if you insist on continuing to occupy the house at Isle Ornsay, which Lord Macdonald has hitherto allowed you free of rent during his lordship's pleasure, you will require to pay rent at the rate of fifty-two pounds per annum,"—a pound a week fine, in fact!

Now, this was dated October 2, and between

this date and Whitsunday, 1881, there intervened two hundred and ninety-nine days (inclusive); consequently the doctor would have to pay forty-two pounds fifteen shillings for his residence—probably the only available one—if he kept his appointment, which is put down at seventy pounds and sixpence a year. There was going to be very little left for him out of his appointment, and he had already been deprived of the "subscription from Armadale Castle."

Whatever may be the social position of the English medical man, he cannot be deprived of his parochial appointment without the sanction of the Local Government Board, which sees that the doctor has a chance of a defence; so that, if ill used, he gets what may be termed "lawful ill usage." But it seems the parochial surgeons of Scotland have no such protection against local malice. Such, then, is the treatment a rural doctor and his wife receive when they chance to offend the local potentate. Comment on my part is as unnecessary as uncalled for; but I venture to think that what I stated last year is quite vindicated by this incident,—at least, to unprejudiced and dispassionate minds.

J. Milner Fothergill.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting of the Society was held at the hall of the College of Physicians, Philadelphia, October 10, 1880, Dr. Albert H. Smith, President of the Society, in the chair. Dr. John H. Packard read a communication entitled "On some Points in Medical Ethics" (see p. 231).

Dr. George H. Hamilton said that this was both an extremely interesting and important subject. The observance of the Code of Ethics is less careful than it should be, and breaches of the Golden Rule seem to be continually on the increase in the intercourse of physicians, and they are now at least five times as frequent as formerly. It is therefore important that some measures should, if possible, be taken by this Society and the State Society and the American Medical Association to correct this growing evil. When the American Medical Association was formed, two of the main objects in view were the improvement of preliminary education prior to attendance upon lectures, and to raise the standard of medical teaching. This has been urged at nearly every one of its meetings, and yet it is notorious that there are far fewer educated persons now in proportion to the whole number of the profession than there were thirty or forty years ago. May we not hope that some stringent measures may be devised more successful in effect than those whose purpose was to improve general education preliminary to the study of medicine?

Dr. Ludlow pointed out the danger of consulting with certain men who afterwards try to supplant the regular medical attendant, and recommended reprisals where this had been done.

Dr. Frank Woodbury said that the paper was timely and discussed subjects that deserved the serious attention of every member of the Society. A change had evidently taken place within the last twenty-five or thirty years in the practice of medicine: the specialist, as noticed by the lecturer, instead of being considered as little better than a charlatan, now occupies a prominent place in the profession, and in many cases deservedly so, as specialism has contributed greatly to the spread of knowledge in several departments of practical medicine. Of late years, however, another and less advantageous change has been gradually taking place that has a decided bearing upon medical ethics and demands investigation. A body of men now entering the profession in order to combine it with pharmacy have apparently little regard for the Code of Ethics, expecting to practise medicine on a par and in competition with other physicians, while still engaged in the sale of patent medicines, homœopathic specifics, and nostrums of all kinds, often being willing to give their advice free for the sake of the profit on the sale of these medicines. This present and prospective degradation of medical practice is all the more to be feared because many of our colleges offer special advantages to druggists to graduate in medicine. As there is a large number of such physician-druggists in Philadelphia already, and their number is steadily increasing, the speaker urged the members to give the subject special thought, in order that some decisive action might be taken by the Society at an early date.

Dr. Packard, in conclusion, said that in the paper he had read he did not pretend to cover the one-hundredth part of the questions which might be brought up for discussion in connection with the Code of Ethics: he had merely attempted to deal with a few points that had struck him from time to time in the course of practice. From some things that had been said in reply, he feared that his meaning had been entirely misunderstood. The question of a few paltry dollars more or less, or whether the case be one of a poor person or a millionaire, should not influence the consultant in regard to his duty. What he had sought to urge was that the case is different when a physician introduces a consultant and when the family select him. A consultant should never indicate by word or look any want of confidence in his brother practitioner: if he does so, he violates the Code of Ethics, and his conscience will tell him that he has injured his fellow-physician. This does not prevent the proper and courteous

expression of individual opinion. In reply to a statement, he said that he did not know what would become of our ethics if one physician should be thought justified in stealing another's patient because he thought that he had been wronged by him. This would amount simply to adopting the lowest instead of the highest standard of conduct. Two wrongs will never make a right; and the *lex talionis* will never serve as a basis for a sound Code.

He closed by again urging the importance of the adoption of a high principle of action, and the maintenance of it by members of the profession in their intercourse with one another and with their patients.

Dr. Henry H. Smith read a communication on "The Injurious Effects of the Constant Use of Baby-Carriages and Bicycles on the Physical Development of the Young" (see page 235).

Dr. M. O'Hara said that the subject of the care of young infants is a most important one, and if the observations of the lecturer are well founded the use of the baby-carriage is to be condemned. He believed, however, that some of the evils referred to, such as bumping over gutters and neglect of the comfort of the infant, could be overcome by having a proper nurse. The better class of carriages are so well provided with springs as to prevent jarring the child. The baby-carriage is of great convenience, especially at the sea-shore, as it enables the child to spend much more of the time in the open air than it would if it had to be carried; the child can in this way sleep with comfort in the open air, which is very desirable in some cases of illness. Babies are not kept in the baby-carriage all the time, but are taken out when they get home, and are then carried around or play on the floor of the nursery: so that their development need not be interfered with. He had used the baby-carriage for years in his own family, and expected to continue to use it, as he had not seen any bad results upon his children from its use.

Dr. Benjamin Lee, in spite of the objections which had been urged, still retained his respect for the baby-carriage, and believed that the posture in which the young infant is placed in the carriage is possibly better than that which it is made to assume when carried in the nurse's arms. In the carriage the child lies upon pillows in a semi-recumbent posture, with the two sides of the body equally and symmetrically supported; whereas if the nurse is stronger in one arm than the other,—and what nurse is not?—the child lies constantly in a distorted position, laying the foundation for a spinal curvature. He thought that the lecturer underrated the amount of force required to carry a baby: in his own family he had noticed that a large baby requires considerable strength, and after carrying the child for a short time he became fatigued, though, in truth, both the nurse and the mother could carry it longer than he could himself.

The point referred to by the lecturer—that the baby is sometimes kept out in the carriage for many hours and allowed to sleep in it—is an advantage rather than an objection: although they do not use their spinal muscles at the time, they are drinking in health and vigor with the fresh air, to use them after they return home, when they are held in the lap or carried on the arm and are thus obliged to make frequent use of the erector spinæ mass of muscles.

Referring to the supposed analogy between railroad concussion and the jolting of baby-carriages, he said that it should be remembered that railroad conductors and trainmen are constantly on their feet and the passenger is sitting erect,—the impulse is thus carried along the spinal column to the base of the brain,—but the infant is lying recumbent, and in a carriage well provided with springs the brain and spinal column are not subject to special movement, and an occasional jolt can be only of slight, if any, importance. The other observation—in regard to the possible connection between club-foot and bicycles—he considered as important and deserving of careful observation.

Dr. W. R. D. Blackwood noticed the frequency of gutters in Philadelphia, which he had often observed in its relation to baby-carriages as careless nurses bounce the babies over them. He had had his attention drawn to the neglect of children by nurses in the public squares, as they are not always minding the baby when out with the child in its carriage. While the nurse is gossiping, the baby is often hanging with its head out of the carriage in the full blaze of the sun, getting ready for an attack of cerebral congestion or meningitis. The strap that runs across in front of the baby to hold it up becomes soon twisted into a rope stretched tightly across the baby's abdomen: so that in going over the gutters the child's head first bounces forward and then backward against the back of the coach in a most idiotic manner, forming the picture of misery and an object of profound sympathy. He thought that it was not necessary for a child under seven months of age to ride in a baby-carriage, and would much prefer the old-fashioned method of giving it an airing in the nurse's arms.

A number of fractures had come to his notice caused by bicycle accidents. He had noticed that the bicycle had been recommended by physicians both as a means of exercise and as a method of transit in country practice. Some English physicians, after using this means of conveyance for several months, have abandoned it. When used in the city on the cobble-stones there must be considerable concussion of the spine, which would be much less in a country district over smooth roads.

Dr. Benjamin Lee said that Dr. Maxwell, of

Wilmington, Delaware, in a conversation upon the subject, had informed him that he had noticed in cholera infantum and summer diarrhœa, that when the little patients had been taken out for a drive in the country with a view of giving them fresh air, they would be brought home very much worse, and sometimes in a fatal state of collapse. He thought that very often in cities, in similar cases, the use of the baby-carriage might result in fatal aggravation of the disease.

Dr. Charles B. Nancrede said that, as regards the shock and concussion of the spinal cord, the members appear to have overlooked the fact that the liability to shock is much less often up to even the twenty-fifth year of age than it is after this time. Owen pointed out many years ago that the epiphyses of the skeleton had the function of preventing concussion of the nervous centres; and many of these epiphyses are not consolidated until maturity. The consolidation of the bones of the skull into what is practically a single bone is also delayed until considerably after puberty. He believed that the results of the motions of the baby-carriage upon the nervous system were much less than had been stated.

The analogy between the baby-jumper and the bicycle is not a true one, on account of the difference in the position of the toes. In the former the toes are directed constantly downwards, the foot being strongly extended; in using the bicycle the toes become the fulcrum, and both the flexor and the extensor muscles are alternately brought into action. Moreover, the results could not be compared, because the boy walks between the times of using the bicycle. The reason that the baby-jumper has such a bad effect is that the bones are not sufficiently ossified to prevent their distortion being effected by the abnormal position of the foot, produced by the constant pull of the contracted muscles; but in a boy of twelve or more years the compensating action of the muscles would generally be sufficient to prevent trouble.

Dr. John H. Packard spoke of his son, who when an infant had tenotomy performed upon him for varus. Last summer, having several times used a bicycle that was too large for him, though only for two days, it was noticed that there was contraction of the plantaris muscle and fascia, causing him to walk on the toe. In all probability it will be necessary to divide the plantar fascia at least, in order to overcome this deformity.

Dr. Henry H. Smith, in concluding the debate, said that he had introduced this subject to the consideration of the Society in order to excite discussion and call out the experience of other members of the Society, and he had been gratified to find that so little had been said in opposition to the opinion expressed in his paper, especially as the recumbent posture of a child in a baby-carriage cannot be sustained by hygienic laws. The upright posture in the nurse's arms favors the action of all the muscles of the back, as well as those of respiration, and therefore the oxygenation of the blood is more perfect. When lying down, and especially when sleeping in the carriage, the motions of the thorax are, as is well known, less frequent, and less oxygen is therefore introduced into the system. Another point in favor of the opinions expressed by one of the speakers in this paper was mentioned in this discussion,—viz., that babies suffering from diarrhœa were injured by riding in a carriage: certainly such shaking and concussion of the viscera does not take place in the nurse's arms. The statement of another speaker—that concussion of the brain and spine cannot readily occur in the carriage, owing to the epiphyses of the bones relieving the spinal cord from concussion—applies only to the upright position of the child when carried or walking, and not to the recumbent posture which it is made to assume when sitting or lying down in the baby-carriage. Even when a child sits up in the carriage it is not so well off as it is on the nurse's arm; and this was shown in the greater activity of that child reported in the paper. Unless the child's muscles are systematically and proportionately exercised, it cannot become as vigorous as it otherwise would when better trained for muscular development.

On motion, a vote of thanks was tendered to Prof. Smith for his interesting communication.

NATURAL VENTILATION AND CONTAGIOUS DISEASES.

Dr. John H. Packard detailed some experiments that he had witnessed recently in New York, showing the passage of gases through solid stone, as in the well-known experiment of Pettenkofer, illuminating gas being forced through a piece of granite simply by the pressure from the meter: it issued in a full stream on the other side so that it could burn with a steady flame. This has a direct bearing upon the spread of infectious diseases; for if the poison passes into the wall there is less to be expected from lime-washing or papering its surface in preventing further outbreaks of a zymotic disease. He also related an instance where a closet in a room persistently retained the odor originally issuing from a case of cancer, although after the death of the patient every precaution had been taken to obtain cleanliness and fresh lime-wash had been applied several times.

Dr. Cleeman did not think that the conclusion in regard to zymotic disease was warranted by the experiment, as there is no evidence offered of the passage of solid particles, but only of gas.

Dr. Perkins mentioned the fact that the odor of a skunk killed in the house was distinctly perceived in an adjoining room,

through a solid wall of masonry two and a half feet thick, within fifteen minutes after the animal had been killed, and remained for at least two years.

Dr. Benj. Lee differed from Dr. Cleeman as regards the inability of solids to pass through masonry. Water passes through walls generally, and, according to Pettenkofer, when the walls are tight they are damp, and a dry house is one where the vapor generated in the house can pass through the walls.

Dr. Nancrede said that gases will pass through brick without any extra pressure being required (Carpenter's "Physiology").

Dr. Cleeman in reply pointed out the fact that the particles of organic matter are not in the same state as watery vapor; gases and liquids readily diffuse, but solids do not.

RED PERSPIRATION IN THE AXILLA.

Dr. Benj. Lee presented a specimen of a peculiar condition of the hairs of the axilla. The patient, a young lady of twenty-five years, had been under treatment for anchylosis of the spine following caries. The general health was good. She called Dr. Lee's attention to the fact that her underwear was much stained in the axillæ by a red perspiration, and upon examining the axilla he found the hairs sparse, stiff, clubbed, and containing red deposits upon them. The habits of the patient were cleanly; no pediculi. The hairs contained no spores, as suggested by Dr. Key, but showed a clear reddish-brown substance irregularly deposited upon them in gum-like lumps. Spore-like bodies were afterwards found, but it was supposed that they were extraneous in their origin.

A communication was presented upon this peculiar condition, during the early part of the present year, by Dr. Axel Key, to the Swedish Medical Society, who described it as follows: "Small, thin, glistening lamellæ, of a pale yellow hue, which soon formed small globular elevations of homogeneous appearance in the main, but with numerous imbedded small glistening spores. The flakes seemed to lie in part on the surface of the hair; in part and predominantly the vegetation pressed in between the outer layers of the epidermic plates of the hair, giving the latter a roughened appearance. No mycelium was discovered."

Two or three similar cases have since been reported in American journals, but no satisfactory explanation of the phenomenon has been suggested.

MR. LAWSON TAIT says that sponge-tents charged each with five-per-cent. solution of oil of cloves will remain in the uterus twenty-four hours without becoming in the least offensive in smell. Other disinfectants do not produce the same result. He also considers sponge-tents safer than the sea-tangle tents for general use.

REVIEWS AND BOOK NOTICES.

DIAGNOSIS AND TREATMENT OF EAR DISEASES. By ALBERT H. BUCK, M.D., New York City, Aural Surgeon to the New York Eye and Ear Infirmary, etc., etc.

The author in his preface makes the statement that he has endeavored to present, in text-book form, a picture of diseases of the ear as they have appeared to him in private and hospital practice, and that in the main he has followed closely the plan of using only the material stored up in his own case-books, and of describing only those methods of treatment which he has tested and found safe and efficient. A work written on such a plan could not be expected to be an exhaustive treatise, but what it lacks in this respect it makes up in practical value, as it is most truly a practical work on ear diseases.

The chapter devoted to diseases of the middle ear (purulent form) and diseases of the mastoid process are especially valuable. A large number of illustrative cases are quoted and details of treatment given, and the entire subject is worked up in the manner that its importance requires.

A careful review of this book quite justifies the statement that it is by far the best work on this subject that has as yet appeared; and it is most creditable that an American should be its author. G. S.

CLINICAL LECTURES AND CASES, WITH COMMENTARIES. By HENRY THOMPSON, M.D., Consulting Physician to the Middlesex Hospital. 8vo, pp. 197. London, J. & A. Churchill, 1880.

Most of the lectures and reports of cases which are contained in this book have already been published in various of the medical periodicals of England, and are therefore presumably more or less known to many of our readers: indeed, many of the subjects treated of are hardly those which a lecturer would specially choose for discussion at the present time, however appropriate they may have been for that purpose ten years ago. For instance, the subject of cerebral rheumatism excited much more interest in 1871 than it does now, when its phenomena and pathology are much better understood.

The author, while admitting that an elevated temperature in cases of cerebral rheumatism is an element of danger, very stoutly contends that it is not the cause of the nervous symptoms, as he says that these very often precede in point of time the hyperpyrexia, and are often present when the temperature does not rise beyond 100°. He nevertheless insists upon the necessity of reducing the temperature when abnormally high, and does not hesitate to recommend the cold bath even in cases complicated with acute bronchitis or pneumonia, asserting that he has never seen any harm result from its use. The term

"cerebral" must, we suppose, continue to be employed to characterize these cases, although it is open to the objection that it tends to perpetuate the error which attributed the symptoms to inflammation of the membranes of the brain, which experience has shown to be rarely, if ever, present. The word "typhoid" has been used, but, although suitable in many cases, would hardly be appropriate in those in which the symptoms assume an almost maniacal violence.

The author also reports, with explanatory remarks, three interesting cases of intracranial abscess which supervened upon otitis, and shows very clearly the connection which exists between these conditions. Other subjects discussed are ulcerative endocarditis, pericarditis, pneumothorax, ascites, and syphilitic disease of the liver.

Although it lacks the freshness one expects in a volume of clinical lectures, the book everywhere abounds in evidence that it is the work of a good observer, and of an accomplished observer, and, as such, is a valuable legacy not merely to the author's old students at the Middlesex Hospital, but to the profession at large. J. H. H.

CUTANEOUS AND VENEREAL MEMORANDA. By HENRY G. PIFFARD, A.M., M.D., Professor of Dermatology, University of the City of New York, and GEORGE HENRY FOX, A.M., M.D., Lecturer on Diseases of the Skin, College of Physicians and Surgeons, New York. Second Edition. New York, William Wood & Co., 1880. 16mo, pp. 310.

The correction of typographical errors, the addition of a few selected formulæ, and some amendments in the nomenclature constitute the principal changes made in this edition of Drs. Piffard and Fox's little book. We regret that these changes in nomenclature have not been more sweeping. The chief fault of the first edition was in its peculiar system of classification and nomenclature, and many of these peculiarities remain in the present edition. The accomplished authors of this little work would have done well had they ranged themselves in harmony with the rest of the modern dermatological world on this subject. Until such a change is made, the book is not one which can be recommended to the student at large, unless he wishes to muddle his brain hopelessly. Within the circle of its authors' teaching, however, it must be a valuable aid to the beginner.

ATLAS OF SKIN DISEASES. By LOUIS A. DUHRING, M.D., Professor of Skin Diseases in the Hospital of the University of Pennsylvania, etc.—Part VIII. Philadelphia, J. B. Lippincott & Co., 1880.

Of the four varieties of disease depicted in this fasciculus of Professor Duhring's Atlas, the first is *erythema multiforme* (*papulosum*). This curious affection is, perhaps, as apt to puzzle the practitioner and lead him astray as any in the long catalogue of skin diseases. Resembling, as it does, so closely some forms of the papular syphiloderm, it is apt to be mistaken for this, and to lead to awkward suspicions and possibly unjust accusations against the unfortunate victim. Dr. Duhring gives a picture of the affection as it occurs on the backs of the hands, and as perfect a representation as could be desired. The picture of *syphiloderma tuberculosum*, which follows, is a good representation of this affection, and the artist has succeeded in rendering the scarring effects on the patient's temple most admirably. The third picture represents a well-marked case of *tinea trichophytina*, the rings on the back of the neck and the broken-off hairs in the scalp being particularly well depicted. The fourth plate is a representation of one form of *psoriasis*, of the variety "nummularis," and is, equally with the others, a work of art and a faithful representation of the disease. V.

A PRACTICAL HAND-BOOK OF MEDICAL CHEMISTRY APPLIED TO CLINICAL RESEARCH AND THE DETECTION OF POISONS. Partly based on "Bowman's Medical Chemistry." By WILLIAM H. GREENE, M.D. Henry C. Lea's Son & Co., Philadelphia, 1880.

As Bowman's well-known "Medical Chemistry" has been out of print for several years, while the demand for such a work still continued, the publishers have brought out the work recast and largely rewritten, although within a slightly smaller compass. On comparing the new work with the last edition of "Bowman," we find very considerable improvement at once apparent. The author of the revision before us has prefaced the course of practical analysis with which Bowman began with a section enumerating the organic proximate principles taking part in the animal economy, and giving full descriptions of all chemical constituents, both normal and abnormal, thus allowing of fuller identification. The analysis of secretions, excretions, etc., then, forms Part II., followed, as in the older work, by the part on the detection of poisons, which therefore is Part III. of the new book.

Among points of merit noticed are, briefly: the tables of urinary sediments, on page 127, are better than the enumeration in the previous edition, and are more fully illustrated by cuts; several methods for the quantitative determination of urea are given, including two newer than Liebig's mercuric-nitrate method; it does not give special schemes for the examination of diabetic and albuminous urine, but the reactions for glucose and albumen and the methods for their quantitative determination are fully given, so that a careful student can use the book to equal advan-

tage, while the danger of mechanically or blindly following a tabular course of analysis is removed.

Among minor deficiencies or blemishes we may mention: first, where it is necessary to mention such names of organic compounds as (on page 54) "neurine is trimethyl-hydroxethylene-ammonium hydrate," a rational or structural formula should be given, as the name does not convey any idea except to the professional chemist; in his descriptions of milk and butter analysis he quotes only older French authorities, and does not give the newer methods of the English analysts; in his arsenic tests he does not recognize the importance of being able to evolve arsenic in alkaline solution, as in Heitzmann's test, nor does he give the convenient modification of Marsh's test by Davy, in which sodium-amalgam is used.

The book is of convenient size, and well printed and bound. SADTLER.

GLEANINGS FROM EXCHANGES.

CÆSAREAN SECTION, WITH REMOVAL OF UTERUS AND OVARIES, SUCCESSFULLY PERFORMED AFTER THE PORRO-MÜLLER METHOD.—Dr. Elliott Richardson, of Philadelphia, reports (*Am. Jour. Med. Sci.*, January, 1881, p. 36) the following case, which is of great interest as being the first successful operation of the kind performed by an English-speaking surgeon. The patient was a dwarf, twenty-five years of age, forty-six inches in height, and weighing eighty-five pounds. It was thought best to select a time for the operation about two weeks anterior to the supposed period for labor to begin, in order to permit ample preparation and to avoid the exhaustion incident to labor. It was thought, too, that the presence of a well-defined cervix would make easier the application of the retaining-ligature at the time of operation. Dr. Richardson avoided giving the preliminary purgative customary in such cases, believing that the disturbed condition of the bowels, or, if opium were subsequently given, the meteorism which would result, would be unfavorable.

The operation, which was performed on the 22d of September, 1880, was begun by an incision in the median line of the abdomen, extending from a point about one and a half inches above the symphysis pubis to a point about four inches above the umbilicus. The incision was about ten inches in length, and was made so exactly in the median line of the abdomen that not more than a teaspoonful of blood was lost from this part of the operation. No hæmostatic was used, and no ligature had to be applied. The abdominal cavity being opened, the uterus could be seen and was drawn out, the abdominal walls being closed immediately and a piece of carbolized flannel wrapped around the base of the uterus. The loop of an écraseur being thrown over, the uterus was tightened at a point a little below the os internum. The uterus was then rapidly opened, the placenta being found directly on the anterior wall, the incision going through it. It was detached, and it and the entire ovum were turned around within the uterine cavity, the membranes ruptured, and the child extracted, followed by the entire removal of the after-birth. Two stout steel pins, about five inches in length and the size of a No. 8 French bougie, were then introduced through the cervix, one passing below, the other above the wire of the écraseur, and diagonally to the line of the abdominal wound. A piece of stout silk cord, previously soaked in carbolized oil, was tied tightly around the cervix between the two pins, exactly in the line of the temporary wire loop, which latter was removed as soon as the permanent ligature was applied, but before it was finally fastened. The silk ligature was wrapped twice around the cervix, and then tied.

The uterus and ovaries were now cut off with scissors at a point about three-quarters of an inch above the ligature, and the stump placed at the lower angle of the abdominal wound. Careful sponging of the cul-de-sac of Douglas with carbolized sponges removed a very small quantity of bloody serum. The abdominal wound was then closed by twelve interrupted silver sutures, four superficial and the remainder deep, enclosing about half an inch of the peritoneum on each side. During the introduction of the deep stitches a flat sponge was placed in the abdominal cavity beneath the flaps to catch and absorb any drop of blood which might escape from the wounds made by the needle.

The wound being closed and the stitches supported by long strips of adhesive plaster, pure liquid carbolic acid was applied carefully to every part of the stump outside of the ligature, plates of lead placed under the pins to prevent undue pressure, and Lister's carbolized gauze applied to the whole extent of the wound and to the exposed stump. This was completely covered with carbolized mackintosh, and the whole kept in place by a flannel binder. No drainage-tube was introduced. The patient was immediately placed in bed, and a hypodermic injection of a quarter of a grain of sulphate of morphia administered. The operation alone occupied forty-five minutes; including anæsthetization and dressing, the entire duration was an hour and a quarter. Lister's antiseptic method was fully carried out.

The history of the case after operation was most satisfactory. For the first ten days the patient's temperature only once rose to 100.4°. On the eleventh day a mild attack of phlegmasia dolens supervened, and the temperature for the three nights succeeding reached

100.6°; convalescence then went on without further interruption. The abdominal wound united by the first intention. The pedicle came away on the eleventh day. The function of the bladder was not at all interfered with. The infant, a vigorous male of five and a half pounds weight, is at present living and well, as also is the mother, three months after operation. Dr. Richardson says, with regard to the effects of the operation, "I have rarely seen less discomfort in a lying-in woman after normal labor."

The advantage of the Müller modification of Porro's method is that it is clean, safe, and easy to perform; not a drop of blood need enter the abdominal cavity. Dr. Richardson attributes his success to the fact that a time was fixed before the period of labor when his eight assistants could be summoned without haste and with due preparation, including the avoidance of contact with contagious disease for two days previous, also to the careful attention to minute details, antiseptic precautions, etc.

ACONITE IN TONSILLITIS.—Dr. John L. Washington (*St. Louis Courier of Medicine*, 1880, p. 436) says, "I have repeatedly verified what Professor Ringer says respecting the effects of aconite in acute tonsillitis, so that I consider it almost a specific. I give to an adult five drops of the tincture of aconite root at once in a little water, and one-fourth as much every twenty minutes afterwards, until the pulse is reduced to ninety and profuse diaphoresis is produced. Then a similar dose is continued hourly. I give a purgative dose of calomel, unless the bowels are loose, in which case, if the tongue is foul, I give a few half-grain doses instead. Hot poultices are applied to both sides of the throat immediately; and, if the patient is willing to pay me for another visit on the next day, if I find pain and swelling still present, which is usually due to neglect of directions, I paint the tonsils and parts surrounding with a solution of nitrate of silver, thirty grains to the ounce, and give him crystals of chlorate of potassa to dissolve in the mouth, to be afterwards swallowed; also, five drops of the tincture of belladonna and two drops of tincture of aconite root every two hours, a combination strongly recommended by both Bartholow and Ringer. In the case of a young man eighteen years of age, whose throat was almost completely closed from the enormous swelling of both tonsils in an acute attack, causing an extreme degree of dyspnœa, and death by suffocation to appear imminent, by means of ten drops of the tincture of aconite root placed on his tongue, and a hot poultice to each side of his throat externally, I have completely relieved the urgent symptoms in thirty minutes, causing very profuse perspiration with a grateful sense of comfortable relaxation. I order patients always to remain in bed until several hours of free action of the skin have passed. I have given aconite to pale, thin children, with moderately weak pulses, and have always found one-half to two-drop doses in the beginning of the attack, repeated every fifteen or twenty minutes, to bring about copious sweating and speedy diminution of the swelling, and have never seen any unpleasant symptom from its use in this manner. If the patient has been, on account of painful or perhaps impossible deglutition, ten or twelve hours without proper nourishment, I order an enema of beef-essence."

A NEW REMEDY IN DIPHTHERIA.—Dr. George Guttmann, of Cronstadt, says, "Knowledge of the physiological action of pilocarpin and of its effect upon bronchial catarrh, giving rise to moist râles, led me to believe that, administered in diphtheria, it might lessen the diphtheritic membrane through the induced abundant salivary secretion, while it would not excite any inflammatory condition. The result of the proposed treatment was above all expectation brilliant and striking. In six cases pilocarpin was administered with cure of the patients in two to four days. In addition, the usual general treatment was followed: quinine, tannin locally, gargles of lime-water, and pepsin. The patients recovered in from two to four days.

"Led by these results, I prescribed pilocarpin in violent pharyngeal cases, angina aphthosa and tonsillaris, always with most happy results, the disease yielding in a short time. In two cases of violent tonsillitis, in which the tonsils were so swollen that water could be taken only with great difficulty, and scarification was positively indicated, not only did the swelling disappear, but the entire group of inflammatory symptoms, the one in twenty-four hours and the other in thirty-six.

"In the few cases of membranous croup that have fallen into my hands during the past fifteen months, pilocarpin has proved a faithful ally, and I believe it will prove as effective as in diphtheria of the fauces.

"Two cases of laryngitis stridula yielded promptly to the same drug, which is safer and more convenient than the usually prescribed emetic."

The formulæ employed by Dr. Guttmann are as follows:

℞ Pilocarpin. muriat., gr. $\frac{1}{3}$—$\frac{2}{3}$;
Pepsin., gr. x ad xii;
Acidi hydrochlor., gtt. ii;
Aquæ dest., ℥iii.
M. Sig.—A teaspoonful hourly for children.

For adults:

Pilocarpin. muriat., gr. $\frac{1}{2}$—$\frac{3}{4}$;
Pepsin., gr. xxx;
Acidi hydrochlor., gtt. iii;
Aquæ dest., ℥viii.
S.—Hourly, a tablespoonful.

He has never observed any undesirable effects of the drug even when it has been continued until complete recovery, possibly

because a small amount of generous wine is given after each dose.—*Berlin. Klin. Woch.*, October 4, 1880; *St. Louis Courier of Medicine*, November, 1880.

Treatment of Diphtheria by Tartaric Acid.—M. Vidal advocates the employment of tartaric acid in diphtheria (*La France Médicale*). Local action on the false membrane is necessary because it has a great tendency to propagation by a sort of auto-inoculation comparable to that which takes place in certain skin diseases. The formula he employs is this: tartaric acid, 10 grammes; glycerin, 15 grammes; distilled mint water, 25 grammes. The tartaric acid acts on the false membrane, which it changes into a gelatinous mass and favors its expulsion. Applications of it should be made about every three hours, and should be followed a short time after by applications of lemon-juice.—*Medical Press and Circular.*

Ipecac Treatment of Jaundice.—Dr. Cook, of Bombay, has obtained good results from large doses (twenty to forty-five grains) of ipecacuanha where small doses had been used without effect. In the ordinary so-called catarrhal jaundice it acts as a specific, and also in one or two cases of hematogenous jaundice good results were obtained by its administration. In a child three years of age twenty grains were given by enema.—*Practitioner*, August, 1880; *St. Louis Courier of Medicine.*

Physiology of the Nervous System.—Dr. Brown-Séquard has recently published the results of certain experiments upon the nervous system, made by himself, which have led to the following conclusions. 1. The appearance of anæsthesia after a lesion of the encephalon no longer affords reason for concluding that the affected part is a perceptive centre or a path for the conductors of sensory impressions. 2. Notwithstanding the very numerous facts which have led him to propose, and to cause to be admitted, the theory that the conductors of sensitive impressions of the limbs cross each other in the medulla, this theory should be rejected. 3. A lateral half of the base of the encephalon might suffice for the transmission of sensitive impressions on both sides of the body, since in the experiments reported by him one-half of the base of the encephalon transmitted, first, the sensory impressions of the right limbs only, then those of the left pelvic limb only.—*British Med. Jour.*, vol. ii., 1880, p. 606.

Resuscitation after Two Hours and Twenty Minutes.—Dr. R. J. Maitland Coffin (*Brit. Med. Jour.*, vol. ii., 1880, p. 659) was called to a case, an hour after delivery, when the child had been allowed to turn on its face and so became asphyxiated. He found a slight flutter at the heart, which ceased in a few minutes. The child was partially wrapped in flannel and placed in front of the fire. Sylvester's method was employed, and at the end of two hours and twenty minutes the child breathed easily, and complete recovery took place.

Fetid Sweating of the Feet.—Dr. Willcox (*Brit. Med. Jour.*, vol. ii., 1880, p. 659) straps the affected portion of the sole of the foot as smoothly as possible with tolerably wide straps of ordinary adhesive plaster,—either emplastrum saponis or emplastrum plumbi. Every part should be completely covered, and with two layers of plaster if the complaint be very bad. The plaster should be taken off and renewed in three or four days, and once again at the expiration of a week, when the skin will be found to be quite healthy.

Extirpation of Three Ovaries.—Dr. Fritz Keppler, of Venice (*Allg. Wien. Zeit.*, No. 36, 1880; *Brit. Med. Jour.*), undertook an operation for the removal of what appeared to be ovarian and tubal degenerate growth of both sides. In the course of the operation, however, it appeared that there was a fully-formed ovary and tube, which were also the seat of disease: so that it was necessary to perform extirpation of the three ovaries and three tubes. Such an anatomical anomaly is, it is stated, previously unknown: so that the case is one of great anatomical as well as surgical interest. The operation was entirely successful.

Dystocia from Coccygeal Anchylosis.—Dr. Alexander Simpson (*Edinburgh Med. Jour.*, November, 1880, p. 386) reports the case of a woman of forty-four, who, menstruating for the last time on the 23d to 26th of July, 1879, and separating from her husband on the 2d of August following, fell in labor on May 14, 1880. On examination, the several segments of the coccyx were found immovably fixed. As labor progressed, some slight mobility of the third and fourth segments of the coccyx supervened, but the first and second remained united to each other and to the sacrum. Labor progressed favorably until the head became arrested on the pelvic floor. After considerable delay, the forceps were applied and the child safely delivered, but with a laceration of the mother's perineum. Mobility was then found to have extended to the point between the first and second segments of the coccyx, but the first still remained adherent to the sacrum. The patient nursed the child and made a good recovery. Dr. Simpson remarks in this case upon the protraction of gestation, there being no doubt that the child was carried *in utero* upwards of two hundred and ninety-two days. He speaks of the tear in the perineum, which ran to the right of the raphé. There was also a laceration in the left nympha towards its upper or anterior extremity. The obliquity of the tears was probably connected with the unusual degree of obliquity of the head as it escaped from the canal, the ordinary degree of rotation of the large head

having been hindered by the projecting coccyx. The chief point of interest, however, was in the coccygeal anchylosis, and Dr. Simpson speaks at some length regarding this peculiarity. According to him, this may be *partial*,—affecting only one joint; the sacro-coccygeal articulation or the terminal segments becoming anchylosed together. If one of the joints remain movable, it is usually that between the first and second segments. Other varieties are the *universal*, all segments being anchylosed, the *complete*, not the slightest mobility remaining, and the *incomplete*, where there is slight mobility. In addition, the point may be misdirected,—turned backward or sidewise. Most frequently, however, the point is turned forward, so as to diminish the conjugate diameter of the pelvic outlet. Among the causes, or probable causes, of coccygeal anchylosis are age and injuries from falling, etc. It is not usually the cause of retarded labor in old primiparæ, imperfect development of the uterine walls being more commonly at fault. Fracture of the parietal bones of the fœtus sometimes results. The diagnosis is made without difficulty by examination. The natural efforts usually overcome the difficulty. Sometimes, however, the coccyx must be broken or the forceps brought into use.

Syphilitic Enlarged Spleen in a Child.—Dr. W. J. Tyson (*Lancet*, vol. ii., 1880, p. 653) reports the following case. A woman, thirty-nine years of age, who had given birth to several children suffering from undoubted syphilitic lesions, gave birth, in May, 1875, to an apparently healthy child. In July following the mother suffered from a breaking down gumma of the soft palate. Two years later the child was seen by Dr. Tyson, who found him with a spleen extending in a downward direction for three and a half inches, reaching the crest of the ileum; in front it approached closely to the umbilicus. The liver was not enlarged. No albumen present in the urine. He was ordered mercury with chalk, one grain every morning and evening, and one grain of iodide of potassium with ten minims of syrup of iodide of iron to an ounce of water, three times a day. After two months of this treatment the spleen was decidedly smaller, and at the end of five months it was only one inch below the margin of the ribs. The medicine was taken more or less regularly for a year, and three years later the child was found in good health and the spleen imperceptible.

Ladies' Sanitary Towels.—Dr. Galabin recommends towels containing a pad of absorbent cotton-wool rendered antiseptic by boracic acid for use during the catamenia and after confinement. They can be made cheaply, costing little more than the price paid for washing the ordinary towel, and can be burned after use.—*British Medical Journal.*

MISCELLANY.

The Brain and Spinal Cord in Extinct Reptiles.—At the late meeting of the National Academy of Sciences in New York, Professor O. C. Marsh, of Yale, who occupied the chair during this autumnal session, read a paper on the dimensions of the brain and spinal cord in some extinct reptiles, in the course of which he spoke of the special interest which attached to the stegosaurus, a mammoth reptile the remains of which he had discovered in Colorado. Five years ago Professor Marsh presented some observations to the Academy which indicated that the more remote the period to which any extinct mammal belonged the smaller would the brain be found, and that as time advanced there had been a gradual increase in the size of the brain, this growth being mainly noticeable in the cerebral or intellectual portion. At the spring session, in April last, he showed that in birds and reptiles also the same law held good. Since then he has examined skeletons of the stegosaurus unearthed in the Rocky Mountains, which, with a body as large as that of an alligator (some of the skeletons measuring thirty feet in length), had a brain-cavity no larger than that of a dog. The peculiar characteristic discovered about this reptile, however, is the existence in the sacral portion of the spinal column of an enormous vaulted chamber like an ordinary brain-box, which is from eight to ten times larger than the brain-cavity in the cranium. Professor Marsh examined a number of these skeletons, and found the same thing in all of them; and as ordinarily the young animal has a brain proportionately larger than that of the grown animal, so here in the skeleton of the young reptile this peculiar cavity is proportionately larger than in the full-sized skeletons. Professor Marsh has never seen anything analogous to this anomaly in any of the land vertebrates.

This is certainly a very curious discovery, the complete explanation of which it may be quite difficult, if not impossible, to arrive at in our present state of knowledge.

At the last meeting of the American Neurological Association, Dr. J. J. Mason, of Newport, reported a series of observations on animals, which seemed to establish the general law that in all vertebrates the diameters of the nuclei of the cells in the inferior horns in the two enlargements of the spinal cord are proportional to the muscular power of the corresponding extremities, the nucleus of each motor cell apparently increasing in size with the growth of the muscular structure which it serves to innervate. Thus, in the frog, with its powerful posterior extremities, the nuclei of the cells of the lumbar enlargement are found to be much larger than those of the cervical enlargement, while in the

gopher turtle the reverse of this is true. Now, if such a law held good in regard to the gross size of the enlargements of the spinal cord, it might possibly throw some light upon the subject, since this gigantic extinct reptile is described to be something like an elongated kangaroo in shape; but even then the enormous size of the sacral cavity, as compared with that of the cranium, would be by no means sufficiently explained, there being no other known extinct or living animal in which such a formation is found to exist.

Professor Marsh, without attempting to arrive at any definite conclusion in regard to the matter, suggested that this curious phenomenon of a "posterior brain-box" might perhaps afford some support to the idea which has been advocated in certain quarters of late,—that the whole nervous system, and not the brain alone, may possibly be the seat of the mind.—*Editorial, Boston Medical and Surgical Journal.*

HERMAN C. EVARTS, M.D., for the past three years assistant-physician at the Friends' Asylum, Frankford, Philadelphia, has recently been appointed Assistant Medical Superintendent to the New York City Asylum for Insane, Blackwell's Island.

THE notorious Dr. John Buchanan (diploma-seller) has been sentenced to pay costs of prosecution and five hundred dollars' fine, also to undergo ten months' imprisonment; his brother-in-law, M. V. Chapman, who, we believe, perjured himself in an effort to effect Buchanan's escape, was sentenced to the same fine and twenty-two months' imprisonment.

INJECTIONS OF CHLOROFORM IN LUMBAGO.—In *La France Médicale* the injection of chloroform in severe cases of lumbago (after the manner of Dr. Bradford) is alluded to. The amount injected varied from three to five drops. This had the effect, in Bradford's cases, of instantly relieving the pain, and after three injections patients were able to work as usual, and were apparently cured.

STRYCHNIA AS A PHYSIOLOGICAL ANTIDOTE TO ALCOHOL.—Dr. Luton, in the *Bulletin de Thérapeutique*, claims that by frequent experiment he has demonstrated that strychnia is the best physiological antidote in cases of chronic alcoholism. He has used hypodermic injections of the sulphate of strychnia in delirium tremens with markedly favorable results, relieving tetanic rigidity and quieting delirium.

POST-MORTEM EXAMINATION NO INJURY.—Ann Farley *vs.* William Carson, M.D.—Error to the Superior Court. The petition recited that James Farley died in the Cincinnati Hospital, January 11, 1879, and that his body was wrongfully withheld from the plaintiff, his widow, and desecrated and mutilated. In the court below, the case was taken from the jury and the petition dismissed upon the ground that it did not contain a cause of action. This action was claimed to be erroneous, and formed the basis of the petition in error.

Judge Avery announced the opinion of the court. He said it was established as the common law that a corpse is the property of no one, although there is a property in monuments and escutcheons of the ancestor vesting in the heirs. To steal a shroud from a corpse is larceny, the property in the shroud being held in the executors of the deceased or the person who buried the body. It was not larceny to steal the body itself; but, at the same time, it was indictable as a misdemeanor. The right in the proper person to the body of a deceased for the purposes of burial—a right correlative to the duty of burial—is recognized by our statutes, Section 3763. The court are not prepared to say, therefore, that the petition did not state facts sufficient to constitute a cause of action. The allegation that the body was desecrated and mutilated might, perhaps, have been made more definite, but, standing as it did, it was sufficiently comprehensive. To include such an injury to the right of decent burial as that would be a reflection upon a court of justice if it were not able to afford redress; but the evidence offered did not make out the allegations of the petition. The only evidence of mutilation was a cut over the liver, the deceased having abscess of the liver, and there was nothing in the evidence to show whether it was made before or after death, although he had been operated upon the night before he died, and had been tapped before he went to the hospital. The petition alleged mutilation after death. No case could exist unless there was such a mutilation as would be an injury to a right, and, as the right was simply the right of a decent interment, there could be no recovery unless in some way there was an infringement upon that right. Judgment affirmed.—*Cincinnati Gazette.*

MODIFICATION OF ESMARCH'S BANDAGE.—Dr. Levis, in a clinical lecture reported in the *Medical Bulletin*, says that the weak point in this bandage is the rubber compressing-tube. He says, "The objection to this apparatus is that it produces a linear constriction, which, being exercised within extremely narrow limits, tends to produce (by compression) a vaso-motor paralysis, the result of which is that sometimes after the completion of the operation hemorrhage sets in and gives more or less trouble to subdue.

"In place of this narrow tube I employ a rubber band made of tubing, the sides of which closely approximate. This band is about one and a half to two inches in width, thus distributing the pressure over a greater extent of surface, and correspondingly decreasing the chances of paralysis and consequent hemorrhage. The ends of this band are lined and surrounded with canvas, and eyelet-holes made in order to permit of lacing if desirable. Since using it I am rarely trou-

bled with hemorrhage following the operation. It controls the circulation fully as well as the more narrow tubing, and is altogether, I think, a great improvement over the old style."

ECZEMA OF THE SCALP AND NOSE.—Neumann, of Vienna, in moist eczema of the hair and scalp, bathes the diseased parts twice a day with the following solution:

Venetian borax,
Crystallized alum, of each 5 parts;
Glycerin, 100 parts.

For this lotion may be substituted a pomade thus formulated:

Venetian borax, one drachm;

Dissolve in a sufficient quantity of glycerin; add Mutton suet,
White wax, of each two drachms;
Olive oil, a sufficient quantity.

ECZEMA INTERTRIGO OF INFANTS.—Dr. H. B. Hodges, in the *British Medical Journal*, recommends the following, after twenty-five years' practice:

℞ Plumb. acetatis, gr. xxx;
Acidi acetici diluti, ℥ij;
Glycerinæ, ℥jss;
Aquæ rosæ ad ℥viij.—M.

He uses no internal medicament.

FOR CATARRH OF BRONCHI OR THROAT.—

℞ Quinidiæ sulph.,
Cinchonidiæ sulph., gr. ix;
Pulv. tragacanthi, gr. xij;
Pulv. althæ radicis, gr. v;
Pulv. gentianæ, gr. vj;
Pulv. santali rub., gr. ij;
Glycerinæ, gr. vj;
Acidi muriatici, gr. vj.

M. Div. in pil. no. xxiv.

Sig.—Four or six pills at bedtime; three pills every two hours during the day.

M. GALEZOWSKI has informed the Paris Société de Médecine Publique et d'Hygiène Professionnelle that he has noted fifty cases of serious accidents to the eye in schools, due to the introduction of steel pens into that organ. He is therefore of the opinion that the use of metallic nibs should be abolished in educational establishments.

INUNCTION OF CASTOR OIL AS A PURGATIVE.—Mr. John Nichol writes to the *British Medical Journal*, telling of a case of acute desquamative nephritis, in a child five years old, where he wished to act speedily upon the bowels. Not being able to induce the child to take any purgatives, he ordered the inunction, with a warm hand over the abdomen, of one-third of an ounce of castor oil. The result was a free action of the bowels five hours afterwards, followed by two other movements during the day.

EMULSION OF CASTOR OIL.—

Castor oil, 4 drachms;
Powdered gum acacia, 80 grains;
Essential oil of almonds, 1 minim;
Simple syrup, 2 drachms;
Water to 2 ounces.

Mix the powder with the oil, then add two drachms of water, and stir till the emulsion is formed, then add the remainder of the water, syrup, and essence.

EMULSION OF TURPENTINE OIL.—

Oil of turpentine, 4 drachms;
Powdered gum acacia, 2 drachms;
Syrup, 2 drachms;
Water to 2 ounces.

Mix the powder with the oil, add half an ounce of water, and stir till the emulsion is formed, then add the remainder of the water and syrup.

Oil of turpentine is considered one of the most troublesome bodies to emulsify: prepared by this form, there is no difficulty.

A MENSTRUUM FOR SALICYLIC ACID.—In the *Louisville Medical News*, May 1, 1880, Dr. Springer states that salicylic acid is readily soluble in effervescing Vichy or Seltzer water, the former, from containing an excess of alkaline carbonates, being preferable. The acid is put into a tumbler first and mixed thoroughly with a small quantity of water, to prevent its floating, and the glass is then filled with the effervescing water and the liquid drunk off. When perfectly dissolved it is said to have a very pleasant, exhilarating, pungent, and sweetish taste.

MICROBES.—Infusoria are giants in comparison with the minute organisms (or microbes) which M. Pasteur has shown to be so much concerned in epidemics and contagious diseases. In pure water the hunt for microbes may or may not be successful. Happily, however, certain chemical agents, especially osmic acid, kill organisms without deforming them, and once killed they sink to the bottom in appreciable quantity (if sufficient water has been used), and may be examined. M. Certes has practised this method successfully. For potable water with little organic matter in it, he uses a one-fifth solution of osmic acid, less than one cubic centimetre sufficing for thirty or forty cubic centimetres of water. For preventing the acid from darkening the tissues too much, some distilled water is added a few minutes after the acid has been in. The deposit may be examined microscopically after some hours (twenty-four, or even forty-eight if the water has been very pure). Coloring reagents (such as Ranvier's picrocarminate, methyl green, eosine, etc.), mixed with diluted glycerin, may also be used with advantage. It is superfluous to insist on the profit which may accrue to natural history and public hygiene from the micrographic analysis of water.

CARBOLIC ACID IN PRURIGO.—M. Lallier, of the St. Louis Hospital, Paris, uses in pruriginous affections of the skin a solution of carbolic acid (two per cent.), to which he adds half an ounce of glycerin, as compresses, or, better, in the form of spray. Its anæsthetic properties cannot be contested, and no inconvenience results from its continued use.

SYNTHESIS OF CITRIC ACID.—MM. Grimaux and Adams have succeeded in preparing citric acid from glycerin. The process is a very

complicated one, but it is said that the acid can by it be made at a cheaper rate than obtained from natural sources. The details of the process may be found in the last number of *The Druggist.*

NEW TEST FOR TRICHINÆ.—A Holstein peasant, uninstructed in microscopical research, and not possessing the requisite instruments of precision, has devised for himself a new test for the presence of trichinæ in pork. When he killed a pig, he was careful to send a portion of it—a ham or a sausage—to his pastor, and then waited the consequences for fourteen days. If his pastor remained healthy, then he felt perfectly easy in his mind, and well assured that his pig fulfilled the requisite conditions of soundness of food, and he proceeded to dispose of it accordingly in his own family. This ingenious method of research has not been considered satisfactory by the district physician.—*British Medical Journal.*

DR. SEGUIN, in *Archives of Medicine* for August, reports two cases of Bright's disease (contracted kidney) in which paroxysmal headache, confined to the occiput, was a marked feature. He calls attention to this phenomenon, as it has never been noticed before.—*St. Louis Courier of Medicine.*

LAST summer there were 98 foreign medical students in Vienna, of whom 38 were Americans.

MARK TWAIN'S RECIPE FOR NEW ENGLAND PIE.—To make this excellent breakfast dish, proceed as follows. Take a sufficiency of water and a sufficiency of flour, and construct a bullet-proof dough. Work this into the form of a disk, with the edges turned up some three-fourths of an inch. Toughen and kiln-dry it a couple of days in a mild but unvarying temperature. Construct a cover for this redoubt in the same way, and of the same material. Fill with stewed dried apples; aggravate with cloves, lemon-peel, and slabs of citron; add two portions of New Orleans sugar; then solder on the lid and set in a safe place until it petrifies. Serve cold at breakfast, and invite your enemy.

TEA raised from seed sent out by the Department of Agriculture has been an article of merchandise in Fayetteville, in this State, and it is grown in Wilmington as an ornamental shrub.—*North Carolina Med. Jour.*

MALFORMATION. — The *British Medical Journal* (vol. ii., 1880, p. 709) quotes, from a Danish source, an account, by Dr. Pippingskiöld, of a strong and fully-developed infant, from whose chest there proceeded two arms with hands and fingers, and, at some distance from them, with an intermediate rudimentary body, perfectly developed nates, with corresponding lower limbs. These four duplicate extremities exhibited some movements during life, but more slowly than the proper limbs of the child. The child died at the end of fourteen days.

OYSTERS AS A POSSIBLE SOURCE OF TYPHOID FEVER.—In the *British Medical Journal*, September, 1880, p. 471, Dr. C. A. Cameron draws attention to the danger of oyster-beds being laid down in the vicinity of the mouths of sewers, seeing that oysters so placed are found with their intestinal canals full of the sewage-matter.

FATAL RESULT OF CHLOROFORM TO THE ADMINISTRATOR.—Dr. Lefevre, a dentist of Oakland, Cal., chloroformed Mrs. Schroeder, of that place. The woman, suffering under the delusion that a felonious assault had been perpetrated during the chloroformization, told her husband, who incontinently shot the doctor. The coroner's jury rendered a verdict charging Schroeder with murder.

BERI-BERI IN SAN FRANCISCO.—Surgeon E. Heber Smith reports eighteen Brazilian man-of-war's men in the Marine Hospital of San Francisco suffering from this curious disease.—*New York Medical Record.*

NOTES AND QUERIES.

ERRATUM.

1118 ARCH STREET, PHILADELPHIA,
January 8, 1881.

EDITOR OF *Philadelphia Medical Times:*

DEAR SIR,—In the *Times* of January 1, 1881, I notice an error in the report of my remarks on the paper of Dr. Wilson, which I trust you will correct in the next issue of the journal. On page 208, at the bottom of the second column, I am made to say that the growth which occurs in Magendie's solution of morphia can be prevented by adding tartaric acid. My statement was that *salicylic* acid would prevent such formation; and, as I have my doubts about the efficacy of tartaric acid, I do not desire to appear to the public as having made an erroneous assertion. The error occurred, I presume, through my not having seen the manuscript of the Proceedings of the County Medical Society.

Yours truly,
JOHN B. ROBERTS.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM DECEMBER 26, 1880, TO JANUARY 8, 1881.

BAILY, E. I., LIEUTENANT-COLONEL AND SURGEON.—Granted leave of absence for two months. S. O. 277, A. G. O., December 30, 1880.

WHITE, C. B., MAJOR AND SURGEON.—Relieved from the duty assigned him in S. O. 229, October 25, 1880, from A. G. O., and to report to the Surgeon-General. S. O. 276, A. G. O., December 29, 1880.

WILLIAMS, J. W., MAJOR AND SURGEON.—To report to the Commanding Officer, Department of Arkansas, for assignment to duty, temporarily, as Medical Director of that Department. S. O. 2, A. G. O., January 5, 1881.

BROWN, J. M., CAPTAIN AND ASSISTANT-SURGEON.—The leave of absence granted him in S. O. 264, December 2, 1880, Department of the Missouri, is extended three months. S. O. 2, c. s., A. G. O.

MEACHAM, F., CAPTAIN AND ASSISTANT-SURGEON.—To report in person to the Commanding General, Department of the East, for assignment to duty. S. O. 278, A. G. O., December 28, 1880.

CARTER, W. F., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Granted leave of absence for one month, with permission to leave the Department. S. O. 265, Department of Texas, December 28, 1880.

PHILADELPHIA, JANUARY 29, 1881.

ORIGINAL COMMUNICATIONS.

FACTS IN REGARD TO THE SWEDISH MOVEMENT-CURE.

BY WILHELM J KARLSIOE,

Graduate of the Royal Gymnastic Central Institute, of Stockholm, Sweden.

(*Revised, and read before the Philadelphia County Medical Society, November* 24, 1880, by BENJAMIN LEE, A.M., M.D.)

IT is well known to all who have read the history of medicine that the Eastern populations of the ancient world employed movements as a curative means, and that the Greeks and Romans, later, extensively applied them as medical agencies, but that with the decay of those peoples their excellent therapeutics were forgotten. If any fault can be found with their modes of exercise, it is that they looked more to the simple development of the muscles than to the regulation of the treatment in accordance with physiological laws. Still, we must confess that the *agonistics* of the Greeks were of value, and have furnished a good basis for the further development of the system.

Although the people of Europe subsequently employed remedial movements, the practice degenerated still more into mere muscle-culture and military drill.

During after-ages medical science passed through many variations, one pretender after another lauding his particular plan which proposed to cure every ailment of the human body. Most of them directed their experiments to the chemical processes of the system, forgetful of the fact that vital phenomena are complex and not confined to one form of force alone.

To a Swede, Peter Henry Ling (1776–1839), is due the honor of having first practically recognized the truth that the movements of the body were based upon physiological laws and produced physiological effects. He considered that inasmuch as vital phenomena were threefold,—the dynamical (manifestations of the mind and will and moral and intellectual powers), the chemical (assimilation, secretion, etc.), and the mechanical (respiration, mastication, circulation, etc.),—the means to modify them ought to include more than the mere chemical agencies. For that reason he devoted himself to the study of the mechanical, not forgetting, however, the dynamical and chemical agencies.

"As our organization," he says, "cannot be complete without the union and harmony of these three orders of phenomena, it follows that this harmony must be health, and an inharmonious relation between them must constitute disease.

"When this harmony is deranged, in order to re-establish it we should endeavor to increase the vital activity of those organs whose functions have a relation to that order of phenomena whose manifestations are decreased or weakened."

Entertaining these physiological views, and fully acquainted with the mechanical treatment of the Greeks and Romans, he considered a knowledge of anatomy necessary for the gymnast, as his own words will show. "Anatomy," he says, "that sacred genesis which shows us the masterpiece of the Creator, and which teaches us at once how little and how great man is, ought to be the constant study of the gymnast. But we ought not to consider the organs of the body as the lifeless forms of a mechanical mass, but as the living, active instruments of the soul which animates the body in every part."

Ling never acknowledged a gymnastic movement to be beneficial until he was able to give an exact account of its effect.

For that reason he held anatomy and physiology as the basis of curative gymnastics, but did not consider an acquaintance with those and other natural sciences sufficient for the gymnast, whose aim should be the elevation of man both in his corporeal and his mental nature. To know the effects of movements upon both the physical and the psychological condition of man was necessary, and this could only be obtained by an exact study of the human being as a whole, on the one hand, and by an analysis of the details of his nature on the other.

After a long period of study and patient labor, Ling succeeded at last in making his new ideas recognized, and the first "Institution for Educational, Military, and Medical Gymnastics" was established in Stockholm at the expense of the Swedish nation. Before he died he had the satisfaction of seeing his mode of treatment enthusiastically appreciated by Sweden and introduced into other countries in Europe.

In accordance with his views, it was

enacted by the Swedish Diet (Congress) that candidates for graduation in the Movement-Cure should be examined in anatomy, physiology, hygiene, the science of human mechanics, pathology, diagnosis, and the principles of the Movement-Cure, and that no one should be accepted as a pupil without passing the "Examination of Maturity," which requires a course of seven years' study, and includes higher mathematics, logarithms, Latin (five years), French, German, English or Greek, ancient and modern history, physics, and chemistry. [I desire to call especial attention to the qualifications demanded of a student of the Movement-Cure in Sweden, and insisted on in good faith, as compared with those required of a student of medicine in this country.—B. L.]

Since 1813, when the Gymnastic Central Institution was first opened, there have been graduates each year, besides medical candidates and physicians from Sweden and foreign countries who study only such branches as are a specialty of the Movement-Cure.

Leaving this short history of the development of the Movement-Cure, I now proceed to define its principles somewhat in detail.

Physical life is dependent on certain distinct processes, such as digestion, respiration, circulation, etc. These processes of life are connected with certain organs; these organs are formed of tissues, and these tissues of cells. Perfect digestion, respiration, circulation, and nervous action take place as long as these organs, tissues, and cells are normal or healthy, and these organs remain healthy as long as nutrition is normal. Hence health is normal nutrition. But if health is normal nutrition, then must abnormal nutrition be the state which is called disease. Abnormal nutrition may decrease until it ceases, when death follows. Hence death is the cessation of nutrition.

With these ideas as a basis, let us try to understand the state of the body in disease. If disease is an abnormal nutrition, this must be owing to the existence of some derangement in the cells or in the tissues, even though it may escape detection.

As anatomy and physiology teach us the condition and the vital functions of our body in a state of health, so do pathological anatomy and pathology teach us the state of the system in disease. That these morbid changes first appear in the cells is now a generally accepted idea; and the results of long practice of the Movement-Cure have shown that if the cells are looked upon as either relaxed or contracted, and the movements directed according to one or the other of these views, many diseased conditions in which chemical treatment alone had been found powerless have been cured or prevented, the chemical and dynamical agencies having been taken into proper consideration. I mentioned before that, according to Ling, health was the harmonious union of the three vital phenomena,—the dynamical, the chemical, and the mechanical. Is this opposed to the opinion that health is normal nutrition? Not at all; for is not normal nutrition the co-operation of the dynamical (nervous power), mechanical (circulation), and chemical (nutritive exchange) phenomena? Hence it is evident that in a diseased state of the system we must try not only to correct that one of these phenomena which gives evidence of disturbance, but to restore all the organs whose functions have a relation to that order of phenomena whose manifestations are either intensified or diminished. The question then arises, What means does the Movement-Cure employ to promote a better nutrition and improve the condition of the cells?

Substances introduced into the body for its nutrition quickly make their way to its most superficial portions, and, while the chemical agencies play an important part in preparing the food for assimilation, the mechanical agencies are not less essential in conveying it to its destination. Are the vessels, in fact, anything but mechanical tubes for the passage of the fluids?

We see plainly that noxious influences of a physical character act from the surface of the body towards the centre. Cold is an external, injurious influence of the air which primarily affects the vessels of the skin and the pituitary membrane, but is very soon transferred to the chest, stomach, or other internal organs. A heavy blow on the chest or head may cause unconsciousness, syncope, collapse, and even death. Whereas if the effect of a mechanical impression did not extend to distant parts, only that which immediately received the impression should be injured or destroyed.

All that we find in our organism, whether

as a part of it or as foreign matter, must at a given moment of time have a fixed volume. Every displacement of any one part, therefore, implies a corresponding change in neighboring parts, propagated to the remotest parts, according to the extent of the primary action. Every little change of attitude, or of the relation of the members of the body to one another, —an external pressure upon a nerve, vein, muscle, or tendon,—must necessarily produce a displacement of neighboring parts and propagate the action more or less strongly into sensitive organs in the proportion of their distance and its intensity, the effect gradually diminishing, like wave-circles on the surface of water.

If, now, this pressure is applied on the largest part of a nerve, vein, etc., according to the force of the impression, the displacement must be larger which is experienced in every blow or external force directed to elastic parts; inelastic tissues receive the first momentum of the force and are destroyed, all their particles being opposed to the force in the same instant of time. Experience shows that a very slight pressure upon a nerve irritates it, that a stronger pressure produces pain, and a still stronger, engorgement and finally paralysis.

Again, we know that we sleep better if we assume a certain position, according to our individuality. What does this indicate, if not the influence of mechanical impressions upon internal organs?

In treatment by the Movement-Cure the position of the patient is the first thing to be observed. The positions most used are standing, kneeling, sitting, lying, half-lying, etc., and in every one of them the trunk or the extremities can be moved in different directions. If we consider each one of these attitudes, we shall find that we are able to place the different parts of the body in an extended, contracted, or passive position. We have many opportunities in daily life to observe the effect of a position. For instance, when the hands are red and heated, if we stretch them upward we find the extended veins emptied and the skin growing pale. The importance of position in procuring sleep is well known. If we further observe the attitude of invalids, we shall find that they, without knowledge of the physiological effects of the positions, always hold and carry themselves so as to get partial relief from pain.

The various kinds of Movements, which we call *Passive*, *Active*, and *Duplicated*, can be administered to the body in every one of the above positions, and hence it is evident that the variations are numerous, and that each may have its special curative effect.

By *Passive Movements* I mean here the exertion of a compressing or extending force from an external source upon the organs of a human body, such as kneading, clapping, fulling, vibrations, and pressing on nerves. The effect of these is to cause the stagnant contents of the vessels to move forward, giving place for a new supply of blood, since the valves of the veins prevent the removed blood from flowing back. The new supply of blood increases chemical action, and the immediate effect is to remove pain, soreness, swelling, redness, and heat, and to equalize the circulation and soothe irritation. These effects are produced without any exertion on the part of the patient, who, on the contrary, receives from the operation a strengthening influence diffused throughout the nervous system, giving new vigor to all the organic manifestations.

It is quite possible to observe the immediate effect of a passive movement by stroking a visible venous trunk either against or in the direction of its current. The first action prevents the onward flow, and the vein becomes very prominent. The second accelerates the blood towards the heart, and the vein dwindles away. The tissues of the body being elastic, it is evident that internal organs can be subjected to the same operation.

As labor is the lot of man, it seems but natural that all the organs of the body should be so constructed as to need a certain amount of exercise; and we are not surprised that experience shows us that too little as well as too much activity is injurious.

Among the organs of our body many are under constant work, as, for example, the heart, the blood-vessels, and the lungs, with their nerves; but a still greater part of our organism—the skeleton, with its ligaments, and the muscular mass, with its nerves—can be moved only by means of the will.

As the muscles form so great a part of the body, it must be important to take them into consideration, for the object not only of preserving health, but also of restoring deranged functions.

If a movement is made by the will and force of the patient, it is called an *active* movement; and if the patient has to overcome the resistance of one or several assistants, it is called a *duplicated* movement.

Now, if we analyze a muscular movement we shall find that three different processes —mechanical, physiological, and chemical —are its evident result. In active and duplicated movements the muscles are alternately contracted and relaxed, and the veins and lymphatic vessels which lie beneath the swelling muscle are compressed. Thus, during contraction the blood is forced from one valve to another towards the heart. When the muscles are relaxed the vessels refill, and are anew compressed by the frequently-recurring pressure of the muscles upon their trunks, thus forcing the blood forward.

Under the use of properly-directed movements the patient is instructed to perform deep inspirations during the muscular contractions, with proportionate expirations. This pump-like motion of the respiratory muscles draws the blood from the veins into the chest in order to supply the vacuum thus created.

But it is not only the muscles which experience the benefit of movements. In nearly every muscular movement some joint is moved, and the extension or compression of its ligaments and cartilages and membranes must provoke a better circulation in those parts. It can be proven by dissection that in those who perform bodily work not only are the muscles more voluminous, but the bones and tendons are more fully developed, than in inactive persons. Exercise, therefore, provokes circulation in all parts of the body which are put in motion. Further, as every muscular movement is performed by the will, it must be evident that the nerves have some share in movements, as the impulse to move a part of our body must be carried from the brain through the spinal cord and the motor nerves to the extremities and surface. Hence muscular movement at the same time that it promotes circulation also provokes nervous flow. This increased nervous action and chemical exchange are only in the motor nerves; but I think that muscular movement can be shown to have also an indirect influence upon the sympathetic and the sensory nerves. A muscular movement has also its chemical effect, as is well proven by physiological experiments. When a muscle contracts, heat is produced; and this heat has actually been measured to the extent of several degrees. If muscular exercise is continued for a considerable length of time, the person himself becomes conscious of an increased temperature, and as a final result perspiration sets in. This heat is the sequel of increased chemical exchanges in parts which are in motion. The muscular movement promoting blood-circulation produces an exchange of the solids and of the fluids of the body, and carbonic acid, lactic acid, etc., are formed, which, if accumulated in the muscle, produce the state which is called weariness. This weariness will disappear, however, when the above-mentioned products are absorbed by the vessels.

The materials thus consumed by exercise must be restored to the system, and the arterial blood, forced forward by the contraction of the walls of the heart, by the contractility of the arteries, and by the peculiar action of the capillary vessels, furnishes this needed supply. The amount of the blood cannot be diminished if the system is to remain healthy. Thus a new supply of nutriment for the blood is required from the digestive organs. This is absorbed by means of the lacteals; whence an increased appetite is the result of movement, as we knew by experience before physiological laws were written.

The chyle is not fit for nutrition, and for that reason it passes through glands where the matter is partially changed before it is emptied into the vena cava to mix with blood on its way to the heart, and still farther on to the lungs, in order to become oxygenated by contact with the air. Hence another effect of muscular movement is increased respiration from reflex action, produced by the impression of venous blood upon the nerves in the lungs. The exchanged noxious matters must be thrown out of the system, and this is partially done by the lungs, which secrete carbonic acid and water. Other noxious matters are separated by the kidneys and the skin. Thus muscular action produces increased activity in all the organs which are concerned in the great process of nutrition. *Duplicated Movements* are the most important, and their curative effect is dependent on *localization*, on the *amount of force* which is used, and on the *time* during which the movement is made. They are *concentric* or *eccentric* accord-

ing as the muscles are contracted or extended during the movement. The effect will be, in the one case to relieve organs suffering from congestion by sending the surplus blood away; in the other, to supply the part acted on with new nutritive blood. The prescription of either of these forms of movements is dependent on the condition of the cells.

By *localization* the effect of a movement is confined to a particular region, or to a separate organ of the body, while the other parts are at rest.

By a judiciously adapted resistance the strength of the patient is equalized with that of the assistant. The patient is pleased to find power of motion where it was previously impossible, and the energies of the system are aroused and encouraged by never allowing the patient to feel that his force is not sufficient to overcome that of the assistant.

The time which a movement occupies, which we designate the *rhythm*, is dependent on the individuality of the patient. The duplicated movements are in general slower than active exercises, giving all the fibrils or elements of the muscle time to participate.

Considering the few hints thus given in regard to the direction of movements according to physiological laws, it will be easily understood that no one without a special education is fitted to give, still less able to prescribe, movements for the cure of diseases, as is so often attempted in this country. No wonder that so many have tried so-called Swedish Movements without benefit, when inexperienced and uneducated manipulators are sent round to rub according to their own crude ideas. It is an indisputable fact that Movements and Massage, which are most important means for regulating the blood-circulation, if applied in opposition to physiological laws will attract the blood to a part already congested or inflamed, and the evil will be aggravated just as surely as if a wrong medicine had been administered.

Though the system is called Movement-Cure, restraint from active exercise is very often necessary. [This brief sentence, I beg leave to remark, contains in a nutshell the *rationale* of that system of treatment which has been fashionable in this city for the past few years under the misleading title of Rest-Cure. The *Rest-Cure* is, in point of fact, the *Movement-Cure*, the rest being merely a more or less necessary accompaniment. Supineness and stuffing are not curative in themselves or by themselves. Movements and Massage are; and Movements and Massage are an essential feature of the Rest-Cure.—B. L.] Great regularity in regard to the treatment, as well as strict attention to the prescribed diet and hygienic rules, is necessary in order to receive the full benefit of the cure. This mode of treatment has a great advantage over other therapeutic methods, from the fact that the patients are always benefited, even if it is impossible to make a complete cure, because the treatment removes pain, congestion, and local swelling, invigorates the muscles and the nerves, causes the lungs to act more freely, regulates the digestion and the blood-circulation, and, in a word, stimulates all the organs to perform their functions without introducing any irritating or toxic agent into the system. What is gained is obtained in nature's own way, by directing the fluids of the body through their natural channels with natural celerity. It is for this reason that disturbed capillary action, and all resulting disorders of the circulation, such as cold hands and feet, rheumatic affections, with their sequelæ of weakness and lameness, hemorrhoidal tumors, disorders of menstruation, and all the different symptoms of disordered digestion (dyspepsia, constipation, flatulence), are among the complaints which most easily yield to this mode of treatment, and that in them a favorable prognosis can always be risked.

In regard to curvature of the spine, if it be dependent upon weakness of the muscles, which are unable to keep the spinal column erect, it is always possible to correct the curvature in from two to six months if the treatment begins before any change has taken place in the vertebræ. In the latter case the Movements will erect the spine partially and stop the further development of the disease by restoring the general health of the patient. It must be the physician's first endeavor to attend to the general health and the causes which have brought on the curvature. That scientific movements must be a powerful means of restoration in this class of cases must be evident to every one, since, whether muscles be on the extremities or on the trunk, exercise must have the same effect on them.

In convalescence after fevers and other acute diseases the Swedish Movements have

been of great benefit in restoring the functions of the system. It must be observed that it is not the primitive disease, but the sequel of it, which is treated in such instances.

Neither excessive weakness nor great age forbids the treatment, as the passive movements are administered without any exertion on the part of the patient. During the seventy years' history of this practice in Europe it has been demonstrated that the aged, by using the treatment a short time once a year, may be rendered to a great extent free from the ailments so common during the latter part of human life.

A cure in ordinary cases of functional disturbance is attained by a treatment of from one to three months' duration, but in higher degrees of curvature of the spine (yet curable), and in constitutional diseases, a course of from four to six months, or longer, is necessary.

The treatment should be administered every day (Sundays excepted). The time required daily is from one to two hours, according to the character of the disease and the condition of the patient.

When we consider that the Movement-Cure affects the most important functions, such as absorption, assimilation, and nutrition, and that these never cease to act as long as the system is in health, it will be easily understood why treatment every day is necessary if good results are to be obtained. Cases occur, indeed, where treatment several times a day would have a much better effect.

I have so far treated of the effect of movement in a general way. Allow me now, by way of example, to contrast the treatment of that most prevalent disease, constipation, by Movements and by medication.

By constipation I mean here that state of the body in which the evacuations are less frequent or less in quantity than in a perfect state of health, and the discharges generally hard and procured with difficulty. The symptoms are, further, variable appetite, acid stomach, headache, cold hands and feet, and, in protracted cases, when large fæcal masses are collected in the rectum, pain in the sciatic nerve and difficulty in urinating.

The causes are indigestible food, sedentary habits, the protracted use of astringent, diuretic, and purgative medicines, mental anxiety, chlorosis, diseases of the spinal cord, weakness of the muscular coat of the intestines and of the abdominal muscles.

The liver is torpid and congested. The alimentary mucous membrane is to some extent congested, whence results deficiency of the required secretions. Now, if the due amount of blood can be brought back to the tissues and the other injurious causes removed, the constipation must yield. I desire to show that the Movement-Cure operates against all these causes.

As before mentioned, no medicines are used, whence this cause of disturbance is avoided. Proper diet is prescribed, and the Movements break up sedentary habits; mental excitement is diminished by directing the treatment so as to draw the nervous fund from the brain and rouse to action the lower portion of the spinal cord by exercising the muscles which get their nervous supply from this part. The liver and the accumulation of fæcal matter are directly operated on by kneading, vibration, and circular stroking (following the course of the colon), which movement removes congestion and promotes fæcal discharges by exciting muscular contractility in the alimentary tube. The respiratory organs are operated on for better oxidation of the blood, which, further, ought to be diverted to the extremities for a wholesome distribution of the circulation. The most obstinate case of constipation rarely fails to yield to a course of this kind persisted in for a few weeks.

Let us now consider the effect of medication in this condition. The drugs introduced into the alimentary canal irritate its nerves, as every substance will which does not consist simply of digestible food. The homogeneous contents of the intestinal tube are mixed with the drug, and the offended absorbent vessels thereupon refuse to perform their functions; hence absorption and nutrition are diminished.

Some portion of the toxic agent is absorbed into the blood, but, passing through the liver, the greater part of it is mixed with serum drawn from the blood, thus enfeebling the nutritive supply of the body, and then returned to the canal.

The mass in the alimentary tube is now acted upon by the emunctories with great power as the nerves are further irritated, and, only partly digested, is forced out of the tube, nature's only way to escape from impending harm.

It is true the alimentary tube has been

emptied for the time by directing the remedy against the most prominent symptoms, as medicine in general is directed; but we see plainly that nothing has been done to remedy the true cause of constipation, and in a very short time after the operation of the purgative the difficulty exists in a greater degree than before.

In the unpromising field of cardiac disease the Swedish Movements have effected some of their most surprising results. The following brief explanation may convey to the profession an idea of the treatment in this class of cases, and the mode in which it is beneficial.

Diseases affecting the heart we naturally divide into two classes, nervous and organic. The nervous affections of the heart are mostly connected with other derangements of the system, as asthenia, chlorosis, diseases of the digestive organs, and pelvic disorders, and are more or less curable in accordance with the curability of the primary cause.

The organic diseases are of quite another character, and though most of them, if they have existed a long time, are incurable, still even in such cases it is possible to give the suffering invalid great relief.

The most common are diseases of the valves, hypertrophy, atrophy, and fatty degeneration. For our present purpose we may consider simply disease of the valves between the left auricle and ventricle, as being the most common. Whether insufficiency or stenosis, the symptoms, as well as the treatment, are very much alike.

In insufficiency of the mitral valve the blood, which ought to be squeezed out of the auricle, partly returns, and in stenosis the heart has not power enough to force the blood out, and a greater or less quantity remains in the cavity. In either case, therefore, the circulation is interfered with in much the same way, and stagnation of blood in the lungs, with shortness of breath, heart-palpitations, and a diminished quantity of blood in the arteries, is the result. The symptoms of the last are principally observed in parts distant from the heart, whence cold hands and feet. To correct this, the heart increases its activity, and this extra work may go on for a long time, the one fault correcting the other, before it is observed by the individual. But at last, as the heart is a muscle and obeys the general law of muscular tissue that too much exercise is injurious, the active fibres become overworked and enfeebled, and the symptoms grow worse, with evidences of stagnation in the large venous circulation, as visible in the bluish complexion.

The functions of the organs nearest to the heart, as the liver, spleen, stomach, and kidneys, gradually become disturbed, and the patient is finally subjected to intense suffering from the accumulation of water in the tissues.

It will naturally be asked, How is it possible to help these sufferers by movements, when even so slight an exercise as walking only increases their discomfort? I answer, we must distinguish sharply between scientific movements and all other forms of exercise. As before observed, the heart endeavors by increased activity to distribute the blood through the system. This gives us a hint for treatment. We must diminish the irritation of the heart arising from the pressure of neighboring parts, and divert the blood to the different organs and distant parts of the body, thus diminishing its work and hence its tendency to abnormal nutrition and hypertrophy.

In the first place, irritation is diminished by keeping the spinal column erect by the due development of its muscles, thus expanding the chest and affording the heart all possible room.

Duplicated movements in attitudes of rest increase circulation, as well in the veins as in the arteries, in parts which are put in motion. The extremities are cold. Exercise of their muscles will therefore be useful. But if, in consequence of the weakness of the patient, these movements are unsuitable, rotations of the joints may be employed to increase the arterial circulation, and upward stroking of the extremities to accelerate the venous flow.

Vibration, kneading, and fulling aid both the circulatory systems. The circulation through the lungs may be assisted by respiratory movements, in connection with clapping and light vibration upon the chest. Passive applications over the abdominal organs will have a good effect in promoting circulation and absorption. The heart itself may be operated on by light clapping and vibration upon the chest, and its movements may be regulated by direct pressure upon either the vagus or the sympathetic nerve.

Whatever the form of disease, whether the power of the heart is diminished or in-

creased, the treatment in all cases ought to be, and unquestionably may be, so administered as to aid the circulation without exciting palpitation or stimulating the contractions of the heart.

In the treatment of patients with heart diseases, ill-instructed manipulators have inflicted much injury by using powerful active movements, and have thus brought the system into disrepute.

I mention this because I know how freely young men, and even children, in this country use gymnastic exercises without previous examination by a physician able to tell them the danger of strong active movements of the arms or trunk if they are afflicted with heart disease. Such cases are in Sweden sent to Movement-Cure institutions, and their records show many instances in which skilled diagnosis had pronounced the disease to be organic, and yet it subsequently appeared that the symptoms arose from weakness of the heart, or of some part of it, as they disappeared under the use of suitable movements.

During the year that I have been in this country I have been struck with the fact that so many sudden deaths occur from heart disease and apoplexy; but, knowing as I now do how gymnastic education is neglected or misapplied in the schools, and, further, having had opportunity to observe how narrow the chest is in most Americans, and how both men and women walk with the chest contracted and the back crooked, either from weakness or from habit, I no longer wonder. The most important organs in our body are thus kept under constant pressure. To prevent this it would seem to be high time to employ systematic movements, as well in public as in private schools, and thus complete education according to the idea of the great Plato. "A good education," he affirms, "is that which assures to the body all the beauty, all the perfection, of which it is capable.

"To secure this beauty, it is only necessary that the body should be developed with perfect symmetry from the earliest infancy.

"If exercise does not keep pace with the growth of the body, it becomes subject to I know not how many infirmities."

Pliny remarks, "The mind is stimulated by movements of the body," and Hoffman, that "we cannot perfect the art of healing till we learn to apply mechanics and hydraulics in medicine."

A CASE OF CHOKED DISK.

BY FREDERIC H. CARRIER, M.D.,

Resident-Surgeon Wills Hospital, Philadelphia, Pa.

FREDERICK McC., æt. 21, born in Philadelphia of illegitimate parentage, a farmer by occupation, was admitted to Wills Hospital August 18, 1880, under the care of Dr. Schell.

About two weeks previously he had been attacked by an erysipelatous swelling on the right side of the face, in the parotid region. This culminated, August 16, in an abscess directly over the condyle of the jaw. The abscess was poulticed and lanced the following day by his attending physician, and about one and a half ounces of pus were removed. He had taken internally the tinct. ferri chlor. Considerable constitutional disturbance had occurred at this time, and been made manifest by heat of skin, furred tongue, etc. He had suffered from intense pain in the right eye, and morphiæ sulphas, gr. $\frac{1}{8}$, hypodermically, had failed to give relief.

His condition at the time of his admission to the hospital, August 18, was as follows. The swelling prevented separation of the jaws beyond half an inch, and the inflammation had invaded the orbital region. The entire side of the face bore a dusky-red appearance, and pitted on pressure at some points near the margin of the scalp.

The right eye was closed by the swelling of the red and puffy lids, and bulged forward, projecting from the orbit about the size of an egg. No fluctuation could be discovered. There was severe pain in the ball, chemosis of the conjunctiva, and slight mucous discharge from the lids, which had commenced August 13.

This eye had been disabled since the age of twelve years, when the patient had suffered from a severe attack of measles. On referring to the hospital records, it was found that he had been an inmate of the house in July, 1879. He had been admitted at that time with central adherent leucoma, causing blindness, for the relief of which iridectomy had been performed by Dr. Schell, with the result of enabling the patient to count fingers at six inches.

In addition to the local symptoms previously mentioned as characterizing his condition at the time of his admission, August 18, 1880, he was feeble and tottering in gait, dull of hearing on the right side, slow of speech and comprehension, pale, and much emaciated. He had always stammered.

The local condition appeared to be that of orbital cellulitis, and he was ordered to bed and given potassium iodide, gr. xx, three times daily, and iced cloths were applied over the eye. His diet was necessarily fluid throughout the duration of his illness.

At the evening visit he complained so bitterly of the ice dressing that a warm flaxseed

poultice was substituted, and continued thereafter throughout the treatment. On August 20, the patient complained of being nervous and wakeful at night. He was ordered potassium bromide, gr. xxx, four times daily, and quiniæ sulphas, gr. iv, four times daily, and the potassium iodide was discontinued. Slight fluctuation having been detected, an incision one and a quarter inches in depth was made about a quarter of an inch anterior to the temporal artery and immediately above the zygomatic process of the temporal bone. A small quantity of sanious pus escaped. He was only permitted to rise from his bed when necessary during the first week.

August 21, the same treatment was continued, and another incision was made half an inch from and a little below the line of the external canthus. A few drachms of pus were evacuated, and a drainage-tube was inserted. The other two openings were probed at each dressing to favor the discharge as much as possible.

The patient seemed slow of comprehension and somewhat peculiar in his manner at this time, and disturbed the other patients by walking about the ward at night. He mentioned that there was a discharge of matter into his mouth, which he referred to the vicinity of the articulation of the jaw on the right side, but his teeth could not be separated sufficiently to permit an examination.

August 22, an abscess was opened in the upper lid. August 24, the drainage-tube was discontinued, no more pus being discharged. Beef-tea and milk-punch were ordered every four hours. He became very restless at night, but did not complain of any pain.

During the next few days the swelling of the face and lids gradually subsided. The patient appeared to be gaining strength, and was permitted to go about the ward and into the garden, but a certain lethargy and dulness were noticeable. He experienced some slight mental illusions, and annoyed the nurse, who slept near him, by asking in the night for anodynes, although quite free from pain.

August 28, slight wandering of the mind was noticed in the evening. August 29, potassium bromide discontinued. August 30, ordered ferri et potassii tartras, gr. v, thrice daily. Urine examined with negative result. Some hebetude noticed. September 1, tinct. ferri chloridum ordered, gtt. x, thrice daily. Ferri et potassii tartras discontinued, and quinine changed to two grains three times daily, instead of four grains four times daily. Abscess opened in lower lid. Patient very weak. September 8, patient drowsy, tongue dry. September 10, much hebetude, very dry tongue, jaws still closed by swelling. Pulse 60, receding; heart normal. Patient very weak; begins to refuse food.

The ophthalmoscope showed at this time a choked disk in the left eye; the top of the swollen nerve could be seen with $+\frac{1}{16}$, although the eye was emmetropic. The vitreous was slightly hazy, and there were some minute hazy spots in the cornea. There was apparent bulging of the bone in the right temporal region. He frequently passed his hand over this spot, but said he had no pain. The swelling of the lids and orbital cellular tissue was so much reduced at this time that the right eye could be seen, and had returned to its natural position in the orbit. Local symptoms all abated. His weakness compelled a resort to rectal alimentation with beef-tea and milk-punch. September 11, patient in a semi-comatose condition, skin bathed in cold sweat, urine passed involuntarily. Dr. Schell came prepared to trephine for pus in the right temporal region, but on consultation with other members of the hospital staff different measures were adopted. An examination of the head of the penis revealed a scar unmistakably syphilitic, and it was deemed advisable to mercurialize the patient at once. He was ordered hydrargyri chloridum mite, gr. $\frac{1}{4}$, every hour, and inunction by unguentum hydrargyri thrice daily. Ferrum dialysatum was substituted for tinct. ferri chloridum, and the quinia was omitted. The pulse was 52, very full,—a typical "brain" pulse. Left-sided paralysis came on during the night. September 12, patient quite comatose. Morning pulse, 106; evening pulse, 150. Death at 3 A.M. September 13.

At the autopsy, nine hours after death, rigor mortis was well established. Head only examined. The dura mater, where it was adherent to the middle fossa of the skull on the right side, showed some effects of inflammation. Three abscesses, one the size of an egg and two smaller ones, were found in the substance of the middle lobe of the brain on the right side. The largest abscess lay within three-eighths of an inch of the outer wall of the brain, and precisely opposite the point where the temporal bone had seemed to bulge and where the pressure of pus had been thought to be indicated before death. The smaller abscesses communicated with the larger, and all three lay close to the base of the brain, being separated from the bone by a thin stratum, perhaps not over one-eighth of an inch in thickness, of cortical tissue, which gave way in the removal of the organ from its natural position. After carefully dissecting the dura mater from its attachments to the middle fossa of the right side, pus was found oozing from the foramen ovale, and a probe pushed gently into the canal caused a small stream of pus to exude. It was found after close examination that the inflammation had passed along the sheath of the inferior maxillary nerve, from the original focus about the ramus of the lower jaw, through the foramen ovale to the brain.

The sheath of the optic nerve was apparently quite healthy. No pus was detected in the orbit.

There was no collection of serum in the sheaths of the optic nerves, the sheaths lying in close apposition to the nervous tissue.

It is evident that the inflammation in this case was of the type of phlegmonous erysipelas, although its steadily localized character and apparent indisposition to spread prevented its true nature from being recognized at the outset. The orbital cellular tissue was, however, fully affected at the date of his reception into the hospital, and had been in that condition for some time previous. Pus never formed in the orbit in such quantity that it could be detected by palpation, but it is very probable that the abscess, which pointed at the outer angle of the orbit, communicated with the orbital cavity, and that whatever pus was produced in the cavity found an exit by way of this abscess when it was opened. Although this could not be demonstrated by the probe, yet the facts that the exophthalmos subsided *pari passu* with the discharge from this point, and that similar terminations to orbital cellulitis are not unknown, give strength to the conclusion.

The inference that the inflammation had passed backward from the orbit to the brain and had there led to the formation of pus, though warranted by the symptoms during life, was proved to be incorrect by the post-mortem examination, in so far as the track which the disease had followed in its inroad upon the cerebrum was concerned. The peculiar route which the disease did follow was quite unanticipated, and, so far as the writer knows, unusual.

It is not known at what stage in the disease the choked disk made its appearance, as the early brain-symptoms, although recalled afterwards, were not at the time of their occurrence of sufficient gravity to attract attention. The fact that the man had always stammered was also to some extent misleading. As is well known, choked disk does not affect the acuity of vision, and, although the right eye was much impaired in its usefulness from previous disease, the vision of the left was as good as ever to the last.

It is worthy of remark that the patient was never known to have either a chill or a spasm of any kind throughout the duration of his illness.

STILLING, of Strasburg, thinks he has demonstrated a spinal root of the optic nerve.

COMPOUND COMMINUTED FRACTURE OF THE SKULL.

Reported by HENRY M. WETHERILL, M.D.

ADMITTED to the surgical ward of the Pennsylvania Hospital, March 6, 1880, under care of Dr. William Hunt, Alexander L., æt. 34, married, laborer.

This man while unloading a vessel fell from the gang-plank which lay between the ship's side and the wharf, striking his head against the latter and falling into the water, from which he was rescued with difficulty and brought to the hospital.

On admission, the patient's condition was noted as follows. He is quite conscious, and converses rationally, not having symptoms of concussion or compression of the brain, but the respirations are shallow and hurried. Over the occipital bone, rather to the left of the median line, is a lacerated contused wound of the scalp two inches in length, including all the tissues to the skull. At the bottom of this wound is felt a depressed fracture of the skull, the depression extending laterally the entire length of the external wound, and the sharp, rough, fractured edge of the occipital bone. There is no bleeding from the ears; but when he coughs or swallows, a liquid resembling bloody serum flows from his nostrils. The conjunctivæ are reddened by effused blood. The pupils are quite normal and respond to light. The pulse is 120, and so weak as to be almost imperceptible. The respirations are shallow, jerky, 36 to the minute. Temperature 97° in the axilla. The external hemorrhage has been trifling, but there is considerable effusion of blood into and under the scalp covering the occipital bone, with great contusion. Careful inspection fails to show any other injury save a few slight contusions.

External warmth was applied, and hot beef-tea given internally. A cool water dressing was applied to the entire head. By the next morning he had rallied well from shock, and was conscious and rational. Respiration and deglutition much embarrassed, but rather less so than when admitted. He had retention of urine, which being drawn was found to be abundant and very pale, sp. gr. 1008, otherwise normal. He complained of constant but not severe headache. Pulse 90 and of fair strength. Ordered him potass. bromid., gr. xx t. d., and restricted liquid diet. Water dressing kept upon head.

Upon the 9th, four days after admission, his condition was about the same: respiration 30; temperature 98.5°. Paralysis of bladder continued, but bowels moved freely without medicine.

Upon the 12th, the pain in head had gone, but the respirations were still much embarrassed, 26 to the minute, temperature 99°. The wound looked well; no spiculæ of bone could be found, nor was there any hernia of cerebral

tissue. Bowels moved spontaneously. Condition of bladder continued. Wound dressed with lint soaked in carbolized oil. His general condition was quite good, and so remained until the 14th, when suddenly, about noon, he became worse, complaining of intense pain in the head, and within an hour the respirations became more rapid and shallow (34 to the minute), and he became quite unconscious; pulse 74, full, no stertor, but facial expression anxious; surface cool, face congested. The pupils, which up to this time had been normal, were now very irregular, sometimes contracted, sometimes dilated, and not acting in unison. Ordered warm pediluvium and friction of extremities with dry mustard, cold applications to head, and internally gave ol. tiglii gtt. ii, followed in four hours by enema containing soap and oil of turpentine. This failed to act. The patient did not return to a state of consciousness, but died in profound coma, death being apparently due to failure of respiration, eight hours after the change in his condition was observed.

Notes of the autopsy, made ten hours after death, as follows. Rigor well marked. The skull is abnormally thin, especially so in the depressions in calvarium for the reception of the Pacchionian bodies, which in this instance are large and numerous. The dura mater very firmly adherent to skull. Considerable amount of subarachnoid effusion, which is purulent. There is a large depressed fracture of all the tables of skull in the left side of occipital bone, from which springs a fissure running up to the temporal bone on the lateral sinus, with several small detached spiculæ of bone, some of which are imbedded in the cerebral substance. There is another fissure starting from this main depression and running into the foramen magnum. Anther fissure starting from the same point and running into the torcular Herophili, at which point are two small spiculæ of the internal table. There is another large depressed fracture of all the tables, with great starring and splintering of inner table, found in the anterior cerebral fossa, fracturing and comminuting the entire roof of the right orbit, from which runs another fissure which crosses and involves both the right and left middle cerebral fossæ. The meninges are freely dissected up from the surface of the convolutions by purulent effusion, so that the convolutions can be readily freed from the membranes and exposed. The entire brain is very much congested; the puncta vasculosa being prominent. The lateral, third and fourth ventricles are distended with purulent, bloody serum, in which float shreds of recent inflammatory lymph. On the left side of the brain in the posterior cerebral lobe, corresponding to a large fissure in the skull, and about one-half inch below the cortical and within the medullary portion of the brain, is an abscess about the size of a walnut, containing about a fluidounce of thick, greenish-yellow pus. The entire base of the skull was occupied by a mass of clot. The other organs were found to be in a normal state, and the bladder was empty.

The condition of the patient during the nine days following the accident afforded but little clue to the overwhelming damage done to the skull and its contents. The only apparent lesion was the depressed fracture of the occipital bone; and the reason that the trephine was not applied and the fragment elevated was that a somewhat shallow and hurried respiration was about the only symptom which the patient presented. It was fortunate that such was the case, as nothing beneficial could have resulted from its application. There was no decided paralysis, either of motion or sensation. The bladder did not act, but the bowels moved freely without medicine. This man was conscious, rational, and knew well the dangerous nature of his injury, expressing a hope that when he recovered his mental condition would be good, so that he could support his family. The expectant treatment was the only one to be thought of in such a case. The patient was not bled, he was not given calomel, he was not purged until the very last, when compression of brain became manifest, nor was his skull subjected to any surgical fumbling. At one time it was a question whether the respiration could not be improved by elevation of the depressed portion of occipital bone; but the application of force to one portion of this skull would have caused great pressure with probable laceration of the brain at many points. What killed this man? Apparently, embarrassed respiration; but there must have been a fresh cause, a new factor at work upon this ninth day.

The abscess, I think, cannot be looked to as precipitating the fatal result, as it was found to be quite circumscribed, the pus not having opened any ventricle.

The enormous blood-clot—which occupied the entire base of the skull, and which must have exerted great pressure upon the most delicate structures—would have proved fatal at an earlier day than the ninth; without, indeed, a fresh intracranial or intra-cerebral hemorrhage had occurred, which factor was absent, as the autopsy showed no signs of recent hemorrhage. It would be an error to state that any one factor was the cause of his sudden demise; but, given a brain sub-

jected to all the pressure and contusion compatible with the exercise of its functions, working along for eight days, plus a sudden effusion into all the ventricles upon the ninth day, result, sudden death, appears to be a reasonable hypothesis when we consider that in injuries of the brain, even of an extensive character, involving considerable inflammation, sometimes the effusion does not occur until after the lapse of five or six days; then, a rather sudden effusion pouring into or upon the cerebral tissues, a fatal result is precipitated.

1237 Arch Street.

TRANSLATIONS.

Diagnosis between Cystitis of the Neck of the Bladder and Prostatitis, and between the Latter and Cowperitis.—*Le Concours Médical* (1880, p. 532) gives the following from Fournier:

Cystitis.	*Prostatitis.*
1. Characteristic vesical tenesmus; frequent and imperious desire to urinate.	1. Vesical tenesmus less marked; rectal tenesmus more noticeable; frequent urination not present.
2. Micturition especially painful at the moment when the last drops of urine are passed.	
3. Excretion of a dysenteric liquid, mixed with pus and blood, at the last moment of urination; pure blood sometimes passed.	3. Nothing of the kind observed.
4. Simple perineal sensibility; irradiating pains towards the anus, less violent than in prostatitis.	4. Deep perineal pains (very severe, and increased on movement), defecation, etc.
5. Prostate normal.	5. To the rectal touch the prostatic tumor is perceptible; very tender, hard, etc.
6. No retention of urine.	6. Dysuria, retention of urine, etc.
7. Few or no general symptoms.	7. General symptoms; fever, loss of appetite, etc., pretty well marked.

Cowperitis is sometimes very hard to distinguish from prostatitis, because the two glands are so near together, and this is especially the case when the disease is somewhat advanced, the whole locality being swollen and phlegmonous. However, careful exploration will usually serve to distinguish the two affections. The passage of an acorn bougie will also serve to show the absence of pain in the neighborhood of the prostate. The course of cowperitis is also different. It shows itself as a phlegmonous tumor adherent to the bulb, limited to the point occupied by Cowper's glands, and having, at first, no connection with the canal of the urethra. The pus in cowperitis points very rapidly towards the perineum, and the vesical symptoms are so slight that some writers have denied the possibility of complete retention in cowperitis.

Anatomical Preparations at the recent Paris Exposition.—A report by Prof. Haivion (*Jour. des Sci. Méd.*, November, 1880, p. 529) says that the exhibition of anatomical preparations for teaching purposes was very complete. Laskowski exhibited specimens injected through the arteries with glycerin and carbolic acid. These specimens preserved their size, flexibility, and color for six to eight months. They could easily be dissected, and are likely to be useful in summer and where cadavers are hard to procure. Prof. Marini, of Naples, exhibited (1) dry specimens having the property of reassuming their freshness and suppleness, with their natural color, when soaked in a special liquid; (2) preparations preserved in a permanently fresh condition; (3) a preparation in which the process of putrefaction had been arrested after twenty days; (4) a heart, having a penetrating wound two centimetres in size, preserving its fresh condition and natural color; (5) petrified specimens, obtained by a process which can be utilized for the preservation of entire bodies; (6) a foot and hand, in the dry state, of great historical interest, Prof. Nélaton having certified that the foot had been seen by him in the dry state in January, 1868, and when again seen, one month later, had resumed its soft and supple condition, so that he could dissect it in part. A similar certificate from Prof. Sappey, dated 1864, accompanies another specimen. This process may in time prove useful in medical teaching and in medical jurisprudence. Prof. Marini keeps his process a secret, having offered it to the Italian government upon terms which have not up to this time been accepted. Dr. Wywod-

zoff, of St. Petersburg, believes this process to be essentially the same as one which he himself has devised. He uses a peculiar apparatus with the following solution: thymol, 45 grains; water, 2 pints; glycerin, 4 pints. He considers this the best mixture for the injection of the entire cadaver, an extremity, or a viscus. Salicylic acid, he thinks, is as good for preserving the cadaver, but must be brought into immediate contact with every portion. The quantity of liquid necessary to embalm a body is nearly one-half its own weight. The cavities must not be opened; the injection must be made very slowly. To inject an extremity, the part should be dipped in hot water and the medullary cavities plugged. M. Wywodzoff gives also further details of his procedure and formula. Among the most interesting of the anatomical and pathological specimens are those models of skin diseases for which Baretta is so famous. He is the founder of the famous museum of the St. Louis Hospital, which now numbers 1100 specimens. Baretta makes a plaster cast of the part to be reproduced, and pours into this his peculiar composition, already colored in various shades so that its color is unchangeable. These models are of the greatest use in places where large skin clinics do not exist. They are sold for an average of fifty francs apiece, and a good collection of fifty is sufficient for teaching purposes.

Normal Ossification.—Kassowitz, in the first part of a work intended to include a study of the osseous system in health and in rachitis and hereditary syphilis, asserts that he believes he has been able to develop a uniform theory of the entire process of ossification which brings all the various peculiarities into unity and does violence to neither logic nor fact.

As to the question, of surgical interest, whether growth takes place by expansion or apposition, Kassowitz declares in favor of an invariable apposition process, regarding expansion as impossible. With regard to the formation of bone-substance, Kassowitz considers that the embryonal structures either develop directly from periosteum to bone or else first become cartilage. He thinks that non-vascularized tissue cannot develop bone. Cartilage is not developed in localities entirely protected from pressure and rubbing; nor is it ever found within firm, bony, diaphyseal tubes. (This view is, however, contested by other observers.) Kassowitz regards the growth of cartilage as always interstitial. As to the resorption of bone, he says that the circulation of tissue "juice" about the blood-vessels hinders the deposit of lime-salts and dissolves the salts which have, under other circumstances, been deposited. He regards the giant cells of Kölliker and Wagner (Kölliker's osteoclasts) as products of change in great part of an originally compact fibrillar structure.—*Cbl. f. Chir.*, 1880, p. 762.

Absorption by the Urethral and Vesical Mucous Membranes.—According to Maas and Pinner (*Cbl. f. Chir.*, 1880, p. 773), repeated researches have been made during the past few years with the view of ascertaining whether the contents of the bladder diffuse with the fluids (blood, lymph, etc.) circulating in its walls. Kaupp found that water was most rapidly absorbed of the various contents of the bladder; urea, also, in considerable quantity; while contained chloride of sodium solution took up fluid from without. According to Wundt, this absorption of water is particularly marked during sweating. Other investigations confirm this. The absorption of poisons by the bladder was noticed by Ségalas and Orfila. Demarquay observed the absorption of iodine; Black, of mercury. Küss, Susini, Alling, and H. Thompson deny the resorptive capability of the vesical mucous membrane.

The consideration of these contradictory results of investigation led Maas and Pinner to experiment for themselves, with the following result. They found that in the healthy human bladder pilocarpin, and also iodine, to a certain physiological degree are absorbed. In catarrh of the bladder of a mild grade the capacity for absorption is increased. The healthy bladder of dogs and rabbits absorbs ferrocyanide of potassium and salicylic acid, as well as cyanide of potassium and strychnia, with considerable rapidity.

Artificial cystitis—excited by injections of turpentine—appears sometimes to hasten absorption, while at other times it delays it. Alling asserts that the reason why all researches into absorption by the bladder are positive in result is because the fluids are either absorbed by the urethral mucous membrane or find their way into the circulation through some abrasion in the

vesical mucous membrane. For this reason our authors cut off the urethral mucous membrane, by ligature at the neck of the bladder, and examined its resorptive faculty separately. They found that the urethral mucous membrane absorbs with great facility, so that the materials used were taken up as quickly as if they had been injected subcutaneously. The pars pendula appears to be most active in absorption: at least experiments upon a patient in whom the penis had been amputated close to the symphysis pubis, on account of carcinoma, showed no absorption in the posterior portion of the urethra.

A New Method of Anæsthetizing the Pharynx.—Rossbach (*Wiener Med. Presse; Cbl. f. Chir.*, 1880, 743), with a view to avoid the inconveniences of the local anæsthetics at present used in the pharynx, has endeavored to benumb the sensibility of these parts by internal medication, administering bromide of sodium in large doses with good effect. Since, however, the condition of stupidity and listlessness produced in the patient greatly interfered with the success of the operation, Rossbach endeavored to cut off the conduction of the sensory nerves of the pharynx, and thus to produce complete anæsthesia of the pharynx. The origin of the sensory branch of the superior laryngeal nerve lies at the point where this passes through the hyo-thyroid membrane, below the knobbed end of the large horn of the hyoid bone, into the pharynx. The nerve is so superficial at this point that a subcutaneous injection of one-tenth grain of morphia on each side at this spot anæsthetizes with the best results. Still simpler, and as certain, is the interruption of conduction by cold, as by means of Richardson's spray-producer, which has been modified by Rossbach so that the spray issues by two little openings, which are arranged to play upon the nerves of both sides at once. Anæsthesia is producd in from one to two minutes.

Hydrops Genu Intermittens.—Under this name Pletzer, of Bremen (*Deutsche Med. Wochens.; Cbl. f. Chir.*, 1880, p. 752), gives the case of an otherwise healthy woman of forty, who for twelve years had suffered from a painful swelling of the right knee-joint, which attacked her suddenly, without obvious cause, was accompanied by considerable fever, and lasted seven to eight days, ending in spontaneous recovery. Three months later the same trouble occurred again, leaving in the same manner. This continued for four years, the attacks occurring at regular intervals. A regular intracapsular effusion into the knee-joint was demonstrated. The usual remedies—quinine, arsenic, iodine douches, etc.—were used in vain. Sulphur and saline baths, however, were employed to some advantage, the attacks growing gradually slighter, but recurring at shorter intervals,—that is, with only eleven days' intermission. The baths having been discontinued, the disease assumed once more the type of three months' interval. Other "cures" were tried without benefit. After a time symptoms of Basedow's disease began to show themselves, and the exudation in the knee-joint ceased to occur. An improvement in the patient's general condition was followed by a relapse of the knee trouble, which recurred at intervals of eleven days again. In February, 1879, the patient became pregnant, when the hydrops disappeared, but symptoms of the Basedow's disease again showed themselves, which did not diminish until the knee began to swell again. Pletzer considers the affection a vaso-motor disturbance.

Nerve-Stretching in Tabes Dorsalis.—Eulenmeyer adds a third successful case to those of Langenbuch and Esmarch (*Cbl. f. Chir.*; from *Cbl. f. Nervenheilk.*, 1880, No. 21). While the two latter surgeons resorted to this procedure because of the severe pain, Eulenmeyer performed the operation with a view to cure the ataxia, a result which Langenbuch and Esmarch accidentally found to follow nerve-stretching in their cases. His patient was a man of thirty-nine with well-developed tabes. The ischiatic nerves on each side were stretched through incisions made in the ischiatic notch. The result was not altogether satisfactory: the patient was enabled to stand, which previously he had not been able to do, but the ataxia remained the same. Eulenmeyer thinks this may have been because the nerves were not stretched enough.

Treatment of Hemorrhoids by Dilatation.—Junqué (*Bull. Gén. de Thérap.; Thèse de Paris*, 1880) recommends forced dilatation for the cure of hemorrhoids. The operation should be performed slowly and by means of the speculum. Junqué says it is without danger.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, JANUARY 29, 1881.

PUBLISHERS' NOTICE.

THE circulation of *The Philadelphia Medical Times* during February and March will be twenty thousand copies. The surplus copies will be mailed direct to physicians in the West and South, affording a special opportunity for advertisers to secure the advantage of an extra circulation without any increase in rates.

EDITORIAL.

AMENITIES OF MEDICAL JOURNALISM.

THE parable of the camel's discomfiture by the needle's eye may with some safety be applied to the attempt of an editor so to conduct a medical journal as to satisfy everybody. The legend of the old man and his ass is very suggestive of the situation, but not half strong enough, for the old man succumbed after his third attempt, while the editor's experience is a perennial wrestle with the opinions of those who watch the game. How easy it seems! Not a critic but could play it better. Not one who could not make things go as smoothly and noiselessly as a Jürgensen watch. Let him try it. He will soon find himself thinking of that shrewd magician who, after showing that a little trick with cards was apparently very simple, said, "It looks easy, doesn't it? Well, practise it sixteen hours a day for eight years, and you'll do it almost as well as I do."

Probably the lookers-on have no idea of the trials with which an editor has to contend; and the impatient critics are commonly those who increase his burdens, —men who feel that he has wronged or snubbed them or is indifferent to them. Their manuscripts have been rejected. "The editor does not know a good thing when he sees it. He is partisan; one-sided; deals in favoritism; doesn't know how to run a journal; is full of unworthy prejudice, etc." Little they imagine how much less trouble it would cost him to publish everything that comes to hand, and thus please all writers, good and bad. How long would a journal exist if no discrimination, no censorship, were devoted to what is sent for publication? In that case imagine the *olla podrida* it would become!

Some men write only when they have something new to say,—something which they hope will be of use to the profession, or give rise to a healthful discussion, or lead to experiment. They write intelligently and unselfishly. Such matter is welcomed. Another, and unfortunately a large, class write for notoriety. They wish to be seen in print. They bid for practice. A fine example of this is Waldenburg's work on inhalation. One would hardly believe it amounts to nearly one thousand pages. An editor recognizes these fellows in what they write. The axe they would grind is easily seen. It is the editor's business to weed out stories so familiar that they are in the very air of medicine. This is not a pleasant task, but the experience is a healthful one for these anxious aspirants for practice, to gain which they are not at all particular as to the how. It certainly is the duty of an editor to give such men their proper place. If his aims are worthy, it is the support of the strong and sincere that he would win, and not the worthless approval of self-seekers who care neither for the success of the journal in which they would publish their fourth-hand matter, nor for the principle which should lead every medical writer to achieve something which will help brother practitioners and not merely cumber a periodical. There are, too, men whose enemy has written a book.

The opportunity being too good to be lost, they ask the publication of reviews in which, with scathing bitterness, they bespatter the unfortunate author with the ink of a criticism so unjust and discourteous that their manuscript is properly discarded by the editor, who thereby incurs unsparing disfavor.

These are extreme cases, of a nature, one would think, easy of management. But there are scores of contingencies to decide which calls for serious thought. The editor would not needlessly offend, neither does he like to feel that he is obliged to propitiate anybody. Still, if he would ever have blue skies and pleasant breezes in his sanctum, he must perforce pocket a certain degree of his independence. Thus it happens on occasion that he temporarily widens the meshes of his censor's sieve in order to give passage to an article which is too dull, too stale, or too youthful for the best interests of his journal. All, however, cannot be grain. It would indeed be a remarkable periodical which never contained chaff, for chaff often clings to the very corn itself.

The number of impulsive communications written by physicians of hasty mood and reflecting on fellow-practitioners is larger than would be believed. The suppression of these is an act of friendship on the part of a careful editor, and the impatience he thus creates in the souls of the writers is, in the majority of instances, succeeded by a feeling of thankfulness for his wisdom. But readers little know how few and rare are the expressions of approval which greet and cheer an editor, even of a successful journal. It is a common and trying attribute of human nature to criticise and condemn without stint, and, it may be, without cause; but praise and approbation, like an elided word, are left to be understood.

Of the unpunctuated, illegible, ungrammatical, tautological manuscripts; of the unreturned proofs intrusted to the hands of authors for correction; of the individuals who come to give gratuitous and useless advice; of the bores who think the journal cannot move without their counsel; of a thousand other trials and annoyances, nothing need be said. These *impedimenta* form a part of the machinery of every journal. When a reader inclines to criticise a journal, let him first try his own hand at the helm, and he will not long remain ignorant of the rocks and shoals which lie in the way of plain sailing. Let it be remembered, too, that a course which to the uninitiated seems to lead directly away from the object to be attained may be merely the symptom of a head-wind which forces the ship into a zigzag route, even though she be steadily nearing the haven.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, DECEMBER 9, 1880.
THE PRESIDENT, Dr. S. W. GROSS, in the chair.

Aneurism of the cœliac axis. Presented by Dr. E. T. BRUEN.

THESE specimens were removed from the body of a colored man, aged about 32, who died in the Philadelphia Hospital a few weeks since. In abstracting my notes on his case I record that a syphilitic history was admitted, but that the individual had been a temperate man in the use of alcoholic drinks.

A pulsation could be felt about two and a half inches below the ensiform cartilage, but a distinct tumor could not be felt. There was no thrill. Careful percussion developed impaired resonance the breadth of the middle finger only. By auscultation, a murmur very prolonged, low-pitched, and of systolic rhythm. There was no bruit, nor could the murmur be heard in the femorals or at the bifurcation of the iliacs; it could not be heard at the back. It was heard first at ensiform cartilage, grew louder till a point two and a half to three inches below the sternum was reached, and then faded away. A deep-seated burning pain was lamented, and also a scattering pain radiating around to the anterior median line along the ribs: this pain he described as sharp, and at times it was much worse than others. Both sorts of pain were relieved by change of posture. His favorite attitude was

lying prone on the face. This helped vastly to mitigate the pain.

A treatment of rest was commenced, and it was designed to place upon him a plaster jacket, commencing the roller high up in the chest and to continue it to the hips. It was hoped that this would aid in fixing the aorta and aid in the treatment of rest in bed, a restricted and selected diet, and the drugs usually employed in these cases. It was decided to apply this dressing on a Wednesday. The day before, the man rose in the morning, expressed himself as feeling quite well, and was engaged in making his toilet, when he suddenly cried out and dropped dead.

Autopsy.—The abdominal cavity was filled with coagulated blood. A saccular aneurism about as large as a good-sized lemon projected from the left antero-lateral surface of the aorta. The walls of the sac were most attenuated; at the periphery of the tumor the external coat was about as thick as a piece of paper, and very brittle from calcareous deposit. The sac, when laid open, was found to be only partially filled with friable clots, not organized into layers, but irregularly disposed over its walls. The rupture occurred at the point most remote from the aorta, at the periphery of the tumor. The orifice communicating with the aorta was very small, about the size of a large hickory-nut. The other parts of the aorta and the heart were normal. The lungs, liver, and kidneys presented a natural appearance.

I would comment briefly on the infinite importance of quiet and rest in the treatment, and the advantage of fixing the aorta by means of the permanent dressing. Certainly the lateral movements of the body would have been much restricted, and the aorta probably saved many a flexion. Only at the last meeting I spoke of the supreme importance to the diagnostician of the prior history of the conditions favoring arteritis, and the evidence of pressure in the path of the aorta, and the percussion-signs of tumor. In addition to what I then said, let me add a word concerning the murmur as present in the case. The absence of bruit, the prolonged low-pitched murmur, with the systole, suggested to me that this was a fusiform aneurism caused by a general dilatation of all the coats of the aorta, especially as the evidence of tumor was so slight so far as percussion was concerned.

The orifice communicating with the aneurism was so small that very little blood probably entered and left the sac; besides, the sac was partially filled with clot, and at the autopsy it lay on the trunk of the vessel, doubtless obstructing its lumen, and I suggest it may have caused the murmur. The ante-mortem inference as to the shape of the aneurism has been, to my mind, sustained by the autopsy.

I show with this case an aneurism exhibited some time ago to this Society, the sacs entirely filled with laminated clot, and in which case there was no murmur, unless the tumor, which projects anteriorly at the second right costal cartilage, was pressed upon so that the calibre of the aorta was lessened. A distant, long, low-pitched systolic murmur, without a taint of bruit, indicates to me that the sac of an aneurism is mostly filled with clots; and, unless I can identify a tumor by palpation or percussion, or by the symptoms of pressure on adjacent organs, I am apt to infer the existence of an aneurism by general dilatation of the coats of the vessel from the above-mentioned murmur. I do not mean to say that these general dilatations do not cause pressure-symptoms, but merely that these are not so pronounced, as a rule. But in this case the murmur deceived me, and a saccular aneurism only half filled with clots exists; but I hope the very small opening leading into the aorta will be deemed a valid reason for the absence of pronounced bruit.

Dr. NANCREDE took exception to the term "abdominal" aneurism, as he thought that a careful examination of the specimen showed conclusively that it was due to a dilatation of the cœliac axis, and did not involve the aorta at all.

Dr. BRUEN thought that this trunk might be partly involved, but was inclined to think that a part of the walls of the aneurism was formed by the aorta.

Dr. NANCREDE explained the anatomical reasons upon which he had founded his opinion, and which he thought were conclusive.

The President said that, as there seemed a difference of opinion on the subject, he would refer the specimen for examination to a special committee consisting of Drs. Bruen, Nancrede, and Formad.

"The committee appointed to examine the tumor agree to pronounce it an aneurism of the cœliac axis rather than aorta proper. This explains the fact that the orifice leading into the aneurism is so small, as it is the dilated cœliac vessel; but remarks in reference to the etiology of the murmur are equally pertinent.

EDWARD T. BRUEN,
C. B. NANCREDE,
H. F. FORMAD."

Spindle-celled sarcoma of the skin. Presented by SAMUEL W. GROSS, M.D.

Records of examples of sarcoma of the skin in the medical journals and references to that disease in the text-books are so very uncommon that I am induced to bring the specimen before the Society.

A married woman, 23 years of age, was brought to my clinic at the Jefferson Medical College Hospital on the 29th of September, 1880, on account of a painless tumor of the integument of the buttock, which was of the size of a small lemon, of a firm elastic consistence, and with a discolored and rugous surface. She first noticed it as a shot-like tubercle about three years previously, and she informed me that she had struck it a few

weeks before, and that the injury was followed by slight bleeding and rapidity of growth.

On section after removal, the cut surfaces were of a rosaceous-yellow shining hue, and had a fibrous tear. Microscopically, the growth was characterized, as can be seen from the accompanying slide, by small spindle cells contained in a homogeneous intercellular substance. Up to the present time the tumor has not recurred.

Dr. DUHRING asked whether in this case there was more than one growth. Although it was now, of course, difficult, or impossible, to determine the exact starting-point of the neoplasm, yet he was inclined to think that its site had been the subcutaneous cellular tissue. Dr. Gross, he remarked, was correct as to the rarity of such growths, all authorities making similar statements. Indeed, Kaposi, the most recent German writer, one who has devoted especial attention to the pathology of skin affections, only devotes a short chapter in his treatise to sarcoma of the skin. He treats of the disseminated pigmented form only, which seems to be the most usual multiple form assumed by sarcoma when attacking the integument. Dr. Duhring knew of only one instance which had been reported in this country within the past ten years. This variety of sarcoma, however, was of such a different form from that presented this evening that he would not enter into any further details.

The whole subject of sarcoma of the skin had been opened up by a case reported by him. He had described the case at the meeting of the American Dermatological Association held at Saratoga in 1878 as an "Inflammatory Fungoid Neoplasm." A year later, at the third meeting of the same Association, he had read a supplemental report upon the case, when, owing to the report of Dr. Heitzmann, he had been inclined to suspect its sarcomatous nature. The disease represented by this case was closely allied to sarcoma, if not true sarcoma. About the same time Geber reported a similar case, also under the caption "Inflammatory Fungoid Neoplasm."

Kaposi, in commenting recently on these cases, says that he has no doubt of their sarcomatous nature. All the cases so far have proved fatal in about two or three years. Dr. Gross had described his case as a "spindle-celled" sarcoma. Dr. Duhring would like to ask whether, in his experience, the round cell was not much the commoner variety.

Dr. GROSS said that he had notes of eight cases of sarcoma of the skin, but that he had been unable to find them in time for the meeting. He was, however, of the impression that Dr. Duhring's statement as to the greater frequency of the round-celled form was correct. The general history of these neoplasms is that they are most common after the fortieth year, that they soon ulcerate, and that they exhibit a decided tendency to recur after removal. With regard to metastases and the final termination he was quite in the dark, as he had been unable to follow his cases. He thought that the apparent rarity of the disease was explicable by the fact that tumors usually come under the care of surgeons, and not of dermatologists. He would call Dr. Duhring's attention to Billroth's "Chirurgische Klinik," in the several volumes of which publication about twenty cases of sarcoma of the skin of various portions of the body are detailed.

Dr. DUHRING called in question the propriety of the term "sarcoma of skin," and thought that its primary seat had been the subcutaneous connective tissue.

Dr. GROSS said that there could be no doubt that it arose from and was limited to the skin, and stated the reasons for his belief.

Dr. FORMAD said that he had lately examined one of many nodules situated in the skin, which had been removed and sent to him by Dr. Nash, of Norfolk, Va. The microscope demonstrated that the growths consisted of round-celled sarcomatous tissue originating in the true skin.

Cancer of liver, with metastasis to the brain and other organs—Destruction of the occipito-temporal convolution without affection of special sense. Exhibited by Dr. H. F. FORMAD for Dr. H. C. WOOD.

T. C., æt. 42, came to the nervous wards of the Philadelphia Hospital early in September, 1880. He stated that he had been a heavy drinker, but had enjoyed good health until the last of August. On September 2 he was seized with giddiness, which lasted over twenty-four hours, but which did not leave him paralyzed. He affirmed that this was the first spell of the sort he ever had, and denied syphilis, headache, or any other known cause or premonitory symptom of the attack. Since the period of unconsciousness he has suffered from continued headache, loss of memory, giddiness, and frequent vomiting, the latter occurring without connection with the state of the stomach as to food, and not rarely in the night, as well as in the daytime.

September 15.—There were no signs of local palsies, and no disorder of vision, and the gait was perfect. There was partial bilateral deafness, which he states was of long standing; there was no anæsthesia. No disorder of the taste or smell was detected, although neither was closely looked for. The right hand exerted a power of 85, the left hand of 92. The liver was found to be very much enlarged, hard, and nodular, and the diagnosis of hepatic cancer was reached. There were no changes in his nervous symptoms, and he was sent to the general medical ward, October 27.

During the last two weeks of his life his mental powers failed very distinctly, his speech became somewhat incoherent, and his memory exceedingly faulty. He died November 10.

Autopsy.—Brain normal, except the under central portion of the posterior lobe of the left side; springing from the membranes in this position was an irregularly ovoid tumor about an inch and a half in the greatest longitudinal and transverse diameters, and about an inch thick. The tumor was of elastic, hard consistence, of dark-red color, and had the appearance of a firm old blood-clot; it was not encapsuled. It had pressed upon and destroyed, by softening, almost the whole of the central portions of the occipito-temporal convolutions. The hippocampus was touched upon, but not altered to any extent. The softening had progressed so far as to open the lateral ventricle, the destruction not involving any of the central ganglia or the crus cerebri.

The membranes of the brain were abnormally thickened everywhere, and the fissures were bound together by inflammatory exudations. The one corner of the tumor had produced a small superficial spot of softening in the cerebellum; the attachments of the tumor to the surrounding tissues were very loose. A decided increase of cerebral fluid, turbid in appearance, was observed. Skull normal.

Examination of the thoracic cavity revealed pericardium and right lung and pleural sac normal. In left pleural cavity extensive adhesions and two pints of a turbid effusion were found; left lung strongly congested, and a wedge-shaped cavity of evidently embolic origin was seen.

Mediastinal and bronchial glands enlarged; heart normal. The abdominal cavity contained over one gallon of a straw-colored liquid; no peritonitis.

Liver very much enlarged; weight nine and a half pounds, of dark-brown color, and studded with the protruding, umbilicated, white nodes peculiar to cancer, varying in size from one-half inch to five inches in diameter. The head of the pancreas was also involved by similar nodes. Mesenteric glands greatly enlarged and noded. Kidneys invaded by a number of small nodules, scattered throughout the capsules as well as the parenchyma of the organs.

Stomach, intestines, rectum, and rest of organs normal.

Microscopic examination by Dr. H. F. Formad determined the structure of the new growth of the liver, of the brain, and of the other organs to be that of a *cylindrical* epithelioma, the primary growth having developed in the liver.

Dr. FORMAD added that the new growth, of the brain especially, showed typically the peculiar cones built up of cylindrical epithelium piercing through a vascular connective tissue in every direction; that at the same time, however, it demonstrated in places well the direct transformation of a cylindrical epithelioma into a simple glandular carcinoma, as described first by Perls, the solid cones of the epithelioma breaking up; and the cylindrical epithelial cells are distinctly seen *transforming* into spheroidal cells, which fill, loosely packed, the alveolar spaces.

Tuberculous growths (tyroma) of cerebellum.

Exhibited by Dr. H. F. FORMAD.

This specimen and some notes of the history I obtained through the kindness of Dr. E. R. Girvin, who will present the interesting history of the case in full to the County Medical Society.

Miss G., aged 21, was never confined to bed with any sickness prior to the malady which terminated fatally. She complained, however, of occasional headache during the last eleven years, which she always located at the occipital region. She received an injury eleven years ago by a fall from a swing, striking this region of the head upon a projecting board, the accident being followed by loss of consciousness, which lasted, however, only a few minutes. With the exception of the periodical localized headache, which started from the time of the injury, she remained perfectly well.

In February, 1880, the paroxysmal headache became of more grave nature, the attacks developed in frequency to one every five or six days, each attack lasting three to four days, the pain radiating over the entire top of the cerebrum and attended with great hyperæsthesia. The skin cool; pulse compressible, thready, and irregular, ranging from 70 to 100. During April, May, and June the patient improved, but subsequently the attacks recurred with increased severity, and were followed by difficulty in vision,—viz., double sight. Examination by Prof. W. F. Norris revealed choked disks affecting both eyes. Later, complete blindness ensued. There was a slight loss of power of left side of body, and sometimes twitching of the muscles of left side of face was noticed, and staggering gait. She complained sometimes of a momentary swinging or rotary sensation. The intellect was clear and the memory not impaired. During August and September the condition of the patient again improved. September 27 the attack suddenly became more severe, and, growing in intensity, terminated by death on October 1. During the last few days of life there was loss of power of deglutition, also of sense of smell, taste, and hearing; general sensibility and clearness of mental faculty were perfect up to death.

A complete autopsy was objected to. I examined only the brain, with the following result:

Skull normal. Dura mater normal, except over the left side of the cerebellum, where it was thickened and adherent to the bone. Pia mater opaque, slightly thickened, and showing evidence of previous strong congestions and repeated effusions.

Examining the cerebellum by section, there were seen a number of yellowish-gray nodes

of a new growth, varying in size from one-fourth to three-fourths of an inch in diameter, located both in the gray and white matter of the left side and at the middle of the cerebellum, in close proximity with, but not involving, the pia mater. The left side of the cerebellum was also thicker than the right. Over the seat of the tumefaction was a distinct localized septomeningitis, and adhesions between the membranes.

The cerebrum was very anæmic, otherwise of perfectly normal appearance in all parts. An increased quantity of fluid was noticed in the lateral ventricles.

Microscopic examination.—Nothing abnormal in cerebrum; the pia mater showed, however, numerous tubercle granulations in the course of the blood-vessels. Examination of new growth of the cerebellum proved it to be of a tuberculous nature, showing the structure of a non-vascular granulation tissue containing numerous nodules, some of which were undergoing cheesy degeneration. Transverse sections of obliterated blood-vessels, and also true giant cells, were conspicuous. The granulations of the periphery of the nodes show a distinct attempt at fibrillation,—the formation of a capsule. The location also of the new growth of such structural elements leaves the diagnosis of *tyroma* beyond doubt, excluding two other possible new formations, the gumma and glioma.

The direct etiological relation of the new growth to the injury received eleven years prior to death is here highly probable, and hence in favor of the theory of inflammatory origin of tumors.

Cancer of stomach. Presented by Dr. J. H. MUSSER.

The patient whose stomach I present for your examination applied to me for treatment the 11th of March of the present year. From him I gleaned the following history.

H. O., æt. 55; butcher; moderate drinker, excessive smoker; has been a hard worker; unfortunate in business, and, of late years, in poor circumstances; has had considerable mental strain; always healthy until present illness; no venereal diseases; family history good; wife died of cancer of the stomach eight months ago.

Present illness was of six months' duration. Increasing languor, debility, and emaciation, dyspnœa on exertion, continual yawning, sleeplessness, and loss of memory, have been noticeable symptoms. What most distressed him, however, was a weight and fulness after meals in the stomach, with flatulence, lasting two or three hours, and only being relieved by forced vomiting; thirst has been very great; constipation persistent and increasing.

His condition when examined was as follows. Large, heavily framed; very much emaciated, having lost seventy pounds; countenance did not indicate suffering from pain but from mental torture; face emaciated; eyes sunken; conjunctiva pale; sclerotic dead-white; lips pale; complexion dirty-yellow; extremities cold; voice weak; speech slow; sighs considerably; mind is sluggish; memory poor; heart and lungs normal; pulse 90, feeble; tongue large, pale, flabby, heavily coated; teeth poor; throat dry, slight pharyngitis; appetite fair; thirst great; after eating, weight and fulness in the stomach; great flatulence; never vomits involuntarily; when he provokes vomiting the matters ejected are the contents of the stomach and greenish fluid, never blood; bowels very costive.

Inspection of abdomen reveals a pulsation between the xiphoid cartilage and the umbilicus, and a distinct prominence to the right of the median line above the umbilicus. *Palpation* defines the bulging to be two and a half inches above the umbilicus, a little to the right of the median line, and extending within one-half inch of the ribs. *Percussion* does not define any resonance between the normal dulness of the liver's margin and the mass. No pain on pressure, and no increase of local heat; no murmur on auscultation. Liver and spleen normal size; urine not examined.

May 1.—Learned from one of his family that he had emaciated very much and become much debilitated.

May 24.—Called to him again, and found him extremely emaciated. Abdomen very scaphoid. Pulsation very visible. Mass observed two inches above umbilicus, between the median line and the ribs. Percussion defines the tumor in that area, extending three inches along the ribs. The size of the mass is greater than when first examined, or the scaphoid state of the abdomen causes it to be more readily outlined. No tenderness on pressure. Paroxysmal pain of a burning or sharp, shooting character. Almost constant vomiting. Matters vomited are the food and an acid, white liquid, burning the fauces and mouth. At times, however, free from vomiting, so that to relieve the distressing sense of fulness he has to provoke it. Tongue large, pale, flabby, coated; pulse 96; bowels constipated. Skin itchy, dry, with a general pustular eruption on it. No sleep; very restless.

May 26.—A powder, given every three hours, containing morph. sulph., gr. $\frac{1}{12}$, sodæ bicarb., lactopeptine, āā gr. ij, pulv. aromat., gr. $\frac{1}{12}$, prescribed on the 24th, gave relief to the pain, stopped the vomiting, caused sleep, and permitted the more liberal use of milk.

The symptoms were all better, though he took scarcely any nourishment, and on the 31st of the month he died of exhaustion.

Post-mortem (twenty-four hours after death).—Body extremely emaciated; abdomen concave; skin of same color as before death, very rough; rigor mortis well marked.

Abdominal cavity alone examined. Tissues bloodless on section; organs in normal position; no ascites.

Stomach very much dilated; vessels con-

gested, both arteries and veins, especially near the pylorus. It contained a dark-gray liquid; no blood. At the cardiac end of the stomach the mucous membrane was very pale, becoming more congested towards the pylorus, with swelling and softening of the mucous membrane and some thickening of the walls towards the pylorus. At the pylorus the walls were much thickened, from one-half to three-fourths of an inch, and projected into the stomach as a shelf. The walls of the duodenum were involved to the extent of two and a half inches from the pylorus. They were infiltrated by a dense, firm mass of tissue, softer an inch from the pylorus than at the pylorus. At some points the thickening was greater, giving the appearance of nodules. Neither the pyloric orifice nor the intestine was occluded, both admitting one finger. I neglected to state that the congested portion of the mucous membrane was bathed with mucus. The mesenteric glands were enlarged.

The *liver* was slightly fatty; weighed two pounds fifteen ounces. The other abdominal organs were natural to a person dying of chronic disease. The pancreas was normal, situated back of the mass, and removed with it.

Remarks.—At the time of the first examination cancer was diagnosed and an unfavorable prognosis given. I was not called in again until shortly before death; hence the absence of notes in the interval. The symptoms and course were characteristic of cancer of the stomach, and the autopsy confirmed the opinion. The microscopical appearances of the tumor are those of a scirrhus, with a few spots of degeneration.

Cirrhosis of the liver and kidneys—Liver deformed—Death from softening of the brain.

Presented by Dr. J. W. MUSSER.

I visited the patient from whom the specimens before you were taken the first time on the 8th of October, 1879. Her condition at that time and the subsequent course of the disease are embodied in the following notes:

Mrs. H., æt. 57, born in Ireland, a resident of Philadelphia, for the past two years living in an intensely malarial district near the Schuylkill. Different members of the family have had malaria the past three months. Married. Eleven children; six living and healthy; the others died of acute disease in early childhood or youth. Circumstances and comforts of life quite moderate. Considerable mental worry from the cares of a large family and on account of husband's intemperance. Habits good.

Father died of "jaundice." Cause of mother's death unknown. A sister died of consumption. No further evidence of hereditary disease.

Always healthy, save an attack of ague twenty years ago, and, for several years, frequent attacks of "biliousness." These attacks were characterized by anorexia, nausea, and vomiting of a yellow-and-green matter, with or without diarrhœa. No syphilis.

For six months patient has suffered from poor appetite, bad taste in the mouth, flatulency and acidity, and irregular bowels. The past three weeks has been quite miserable, being without appetite and very weak. Cramp-like pains, coldness and heaviness of the lower limbs have troubled her for a week, while for two days she has been vomiting.

At present (October 8) she is quite weak, somewhat emaciated; extremities cold; skin of trunk warm and harsh, of a dark, muddy color; face of same color, with injected capillaries of the cheek; conjunctiva yellowish; heart normal; pulse 130, weak; lungs normal; breathing hurried, thirty to the minute. The hurried pulse and respirations are due to the exhaustion from vomiting. Nausea is constant; vomiting occurs every half-hour. The matter vomited is a yellowish, sour liquid, with flakes of mucus in it; no blood. Sourness over stomach, but no pain.

Inspection of abdomen reveals a slight general enlargement, with localized bulging in the right hypochondrium. No enlarged veins. On palpation, it is found that a smooth, hard tumor occupies the following area: Extending from the outer border of the right rectus muscle to the axillary line. The lower margin is, at the outer border of the right rectus, one inch above a horizontal line through the umbilicus from left to right. In the nipple-line it extends to the line, in the axillary region to an inch above the crest of the ilium. No pain attends its handling. The upper boundary of the liver begins at the fifth rib on deep, in the sixth interspace on superficial, percussion. From thence dulness extends to the margin defined by palpation, being continuous with the tumor-dulness. The left hepatic lobe is not enlarged. Normal liver-dulness not increased posteriorly. With inspiration and expiration the entire mass moves, so that it is, with the evidence of percussion, connected with the liver. Spleen is not enlarged. Bowels are costive.

Appropriate diet and sedatives soon allayed the gastric symptoms, and in three days she was ordered cinchona, strychnia, and muriatic acid, and a regulated diet.

About three weeks afterwards her urine burned her very much when passed. It was found to be of an acid reaction, a dark-red color, without albumen or sugar, containing urates and bile-pigment.

In November she had a sudden, profuse, painless uterine hemorrhage. Her menses had ceased years ago. This was the only hemorrhage throughout her illness.

I saw her again December 11. She had emaciated somewhat. She was very weak. Her eyes were jaundiced, the capillaries of the face congested, and the skin of the face dark or bronzed, as previously noted. She had some slight fever, and a pulse of 110.

Her appetite was poor, tongue coated brownish, red and glazed at the edges, thirst great, bowels regular. Would not allow an abdominal examination. Suffers from pain in the loins. Urine is scanty. A dry, hacking cough annoys her very much. At times a dark-yellow expectoration. No physical signs of bronchitis. Slight œdema of feet.

12th.—Œdema subsided somewhat. Nausea and vomiting all night. Vomited matter at first like the yolk of an egg, later a watery fluid with flashes of green-tinged mucus floating in it and green masses at the bottom of the vessel.

13th.—Vomiting better. No fever. Pulse 100. Liver as before noted; descends three inches, and is pushed to left by the ilium. No œdema. Colic and diarrhœa last night. Much stronger. Urged continuance of the previously ordered acid tonic.

23d.—Another gastric attack, as previously.

January 16, 1880.—Noted as follows: Been visiting her every week, and find mind gradually failing. Wanders readily from a subject, talks of unreal occurrences, and of nonsensical matters. No memory. Sleeps poorly. Slight headache. Urine scanty, very red; specific gravity 1020; slight albumen. No jaundice. Considerable tympanitis.

21st.—Urine high-colored, acid; slight amount of albumen; no sugar; bile-salts and pigment. Microscopically, bladder-epithelium, pus, uric acid, and an abundance of phosphates. Growing weaker and weaker. Dry, brown tongue; slight gastric pain; no vomiting; regular bowels; slight ascites; no headache. Poor sleep; wandering delirium; refers to imaginary occurrences. Is continually enacting the movement of winding a spool of thread.

31st.—Peritoneal fluid increased. Pain in abdomen. Temperature not elevated. Pulse 120. "Some smothering about the heart." Mind less composed than before. Urine scanty.

February 2, 1880.—Urine scanty; eight ounces passed in twenty-four hours; high-colored. Microscopically, red blood-cells in abundance, a few white cells, epithelium from kidneys, ureters, bladder, and vagina; a few crystals of oxalate of lime. Urates, phosphates, and tube-casts absent; bile-pigment in abundance. Chemically, bile, one-sixteenth albumen; no sugar.

5th.—Ascites increased. Tongue flabby, red, and fissured. Vomited once,—bile. Bowels regular, fæces dark-colored. Pulse 120. No œdema of feet. Feeble; more stupid. Recognizes with difficulty, and comprehends poorly. At apex of heart a "murmurish" sound.

March 2.—Vomiting a dirty-yellowish, offensive, copious matter. Diarrhœa past two days; stools thin, clayey, offensive. Urine passed involuntarily. Is semi-conscious; aroused with difficulty, and murmurs unintelligibly. Lies on right side, with the knees and legs drawn up and head bent to the chest; lack of co-ordination in movements for a week. Past three weeks face has had the appearance of dementia, as in cerebral softening; not the cirrhotic countenance.

12th.—Pulse 100, moderately strong, regular; respiration 32, short. Twitching of the muscles of limbs. Can be aroused. Some hyperæsthesia; slight fever. Does not take food; urine and fæces passed involuntarily.

Became more and more unconscious, and died on the 13th in coma.

Autopsy.—Examined twenty-four hours after death, Dr. W. E. Hughes assisting.

Rigor mortis not well marked; body not extremely emaciated; skin dark, dirty color; no anasarca or jaundice.

Abdominal walls one and a half inches thick; fat moderately abundant. Cavity of abdomen almost filled with a clear, light straw-colored fluid; no flakes of lymph, and no adhesions; no congestion of the visceral or parietal peritoneum. Liver not displaced, occupied the position defined during life; other organs in normal position. The liver was not nodular, but its surface was granular, and on section it was dense and firm, granular with increase of connective tissue. A slight indentation marked this. The right lobe measured five inches from right to left, the left three inches. From above downwards the right lobe measured seven and a half inches, the left three inches. The right lobe was two and a quarter inches thick, the left two inches. It weighed two pounds two and a half ounces. Spleen normal in size, dense. Kidneys enlarged, congested, weighed ten ounces each; capsule easily removed; proportion between cortical and medullary portion normal. Mucous membrane of stomach and intestines pale.

Heart, left ventricle contracted; mitral valve slightly thickened. Lungs slightly œdematous. Brain not examined.

Fluid of peritoneum contained albumen, sugar, and urea. Kidneys, microscopically, were congested, and in early stages of cirrhosis. Liver markedly cirrhotic.

Remarks.—The cause of the enlargement only of the right lobe of the liver, and only of the anterior portion, at first puzzled me. It could not be a hydatid, or a purulent or serous collection between the liver and diaphragm pushing the organ down, for the lungs were not encroached upon, nor were there any other confirming symptoms of such conditions, as fluctuation or fever. There were no symptoms or signs of disease of surrounding organs, as the kidneys, to cause a dislocation of the liver. Hydatids, abscess, and cancer were excluded, from absence of symptoms peculiar to each, although the indefinite cause of the father's death made me consider cancer carefully. The knowledge of the patient's habit of tippling, which I learned after her death, would have confirmed my suspicion of

cirrhosis. Before the symptoms of the second stage of cirrhosis developed it was only suspected; for in the first stage the liver is enlarged uniformly; this was of one lobe. The symptoms of the second stage confirmed my suspicion, although there was no contraction.

The commencing Bright's disease was aggravated by the ascites, no doubt. The amount of fluid was never so great as to interfere with respiration or cardiac action. The state of the mind forbade tapping.

The cause of death was undoubtedly softening of the brain. The renal complication was not sufficiently grave to cause uræmia. The cirrhotic cachexia was not sufficiently developed to produce the cerebral symptoms of the later stage of cirrhosis.

PHILADELPHIA ACADEMY OF SURGERY.

MEETING OF DECEMBER 6, 1880.

The President, DR. S. D. GROSS, in the Chair.

CASES OF CLUB-FOOT.

DR. T. G. MORTON exhibited some cases of club-foot in which treatment had been instituted soon after birth. The method of treatment consisted in manipulation and the wearing of proper shoes, without tenotomy. The cases had resulted very satisfactorily, and were presented in illustration of the remarks made by Dr. Morton at previous meetings of the Academy.

Dr. S. D. Gross remarked that tenotomy for the cure of talipes was apparently harmless and gave good results, and, although death might occur in exceptional cases on account of improper after-treatment, it certainly was a termination that was never to be expected.

Dr. Morton had once seen erysipelas and deep abscess follow tenotomy, but this is very unusual. The trouble that occurred in such cases was due, as a rule, to the neglect of proper after-treatment on the part of the parents. Hence, in cases seen in infancy he attempted, and usually was able, to cure the talipes without tenotomy, except in some instances of equinus, when he was obliged to divide the tendo Achillis. This he did when the child began to walk.

Dr. S. W. Gross thought the ordinary method of operating useless, and the usual method of applying the shoe a barbarity: still, he believed that division of the tendo Achillis was preferable, because it hastened cure. The varus should be overcome by manipulation first, and the heel then brought down. After manipulation has been begun, the foot may be kept in place by adhesive plaster carried around the foot and up the leg.

Dr. D. Hayes Agnew knew of death occurring after division of the soleus in the calf, probably on account of the posterior tibial artery having been divided. In his opinion, no operation is wise at an earlier age than one year, but in the mean time it is well to correct deformity and develop the paralyzed muscles by manipulation.

Dr. De F. Willard considered it hardly proper to disrupt at an early age, because inflammation might occur, and manipulation continued through a series of weeks would accomplish the same purpose.

POSTURAL TREATMENT OF FRACTURE OF THE CLAVICLE.

Dr. R. J. Levis presented the last three cases of fracture of the clavicle that had been under his care in the Pennsylvania Hospital, in order to demonstrate the superiority of the postural method of treatment. The cases admitted are usually liable to great displacement, on account of the muscular development of the patients, but by this manner of managing the fracture union is obtained with so little deformity that the seat of fracture is often difficult of detection. The patient, on admission, is placed in bed in the supine position, with a pad under the inferior angle of the scapula to fix it and make it a lever; and then, by slightly elevating the head, to relax the sterno-mastoid, and carrying the arm of the injured side across the chest, accurate apposition of the fragments is usually obtained. If it is found necessary to carry the outer fragment more strongly backwards, a bag of shot or sand is laid upon the point of the shoulder. If this line of treatment is adopted for ten days, sufficient fixedness and solidity are obtained to permit the subsequent management of the fracture to be conducted with the patient in the erect position without any special apparatus. The cessation of muscular irritability and the partial union by soft callus render displacement improbable after this lapse of time, and an ordinary sling to support the arm is sufficient. This manner of dealing with fractured clavicle was recommended by Hartshorne, and seems to yield excellent results.

Dr. John H. Packard remarked that when the clavicle is broken the serratus magnus muscle drags the scapula forward, and it is because the method described prevents this action that the good results ascribed to it are obtained. When the clavicle is intact, the scapular and clavicular movements take place around the sterno-clavicular articulation.

Dr. T. G. Morton had seen Dr. Edward Hartshorne employ this method in the Pennsylvania Hospital many years ago. He placed a pad on the inferior angle of the scapula and another on the point of the shoulder to draw the acromial end of the clavicle outwards.

Dr. A. Hewson, on looking at the patients, who still wore the retentive bandages, expressed his opinion that the shoulder of the

affected side was lower than the sound one in each of the three cases presented for examination.

Dr. Levis stated that this was only apparent, and due to want of similarity in the posture of the two arms.

TRIPLE CYST OF NECK CURED BY INCISION AND DRAINAGE.

Dr. T. G. Morton presented a patient who had been treated for a cystic tumor of the neck. It had existed about four years, and was incised with a bistoury on October 23, 1880, when it was found to consist of three distinct cysts. Thick serous fluid, of a specific gravity of 1024, was evacuated, and a drainage-tube inserted. In five or six days the tube was removed, but subsequently the tumor became tense, respiration difficult, and the temperature reached 103°. Two openings were made with a trocar, and fxxʒiv of purulent fluid allowed to escape. After some difficulty in restraining superficial bleeding, caused by the trocar dividing a vessel, drainage was instituted and carbolized dressings applied. From this time the man continued to improve, and recovered without further trouble.

CYSTIC BRONCHOCELE CURED BY TAPPING AND DRAINAGE.

Dr. Morton also exhibited a woman with cystic bronchocele, who had been successfully treated by tapping and the introduction of a drainage-tube. The cyst had been repeatedly tapped by several operators, but finally suppuration occurred, and, as threatening symptoms were present, he introduced the trocar and treated by drainage. There was now scarcely any tumor to be found, on examination.

IMPROVED PATELLA-HOOKS.

Dr. R. J. Levis showed a recent improvement of his separated patella-hooks, which consisted in substituting for the long screw an ordinary thumb-screw to clamp the two hooks together after the fragments had been drawn into close apposition by them.

A SUBSTITUTE FOR HUTCHISON'S METHOD OF TREATING COXALGIA.

Dr. Levis also presented a patient under treatment for coxalgia, where extension was obtained by flexing the knee, encasing it in a silicate-of-sodium bandage, and allowing the man to walk with crutches. The flexion prevented the foot from touching the ground, and the weight of the limb kept up extension. At night the laced silicate splint was removed and weight-extension applied. This was merely a modification of Hutchison's plan, in which the sole of the shoe of the sound limb is thickened in order that the diseased limb may swing clear of the ground and give extension by its own weight when the patient walks with crutches. The method shown seemed to avoid the awkward elevation on the sound side. Weights could be attached to the flexed knee if more powerful extension was desirable.

CONGENITAL DISLOCATION OF BOTH CRYSTALLINE LENSES (ECTOPIA LENTIS).

Dr. John B. Roberts presented this case, with the following history:

I am told that this boy, aged 12 years, has had defective vision from infancy, though he has learned to read by going to school. Inspection at his first visit showed me at once some divergence of the axis of the left eye; and, after dilatation of the pupils with atropia, the cause of his imperfect vision was apparent. Both lenses were seen, by oblique illumination, to occupy the upper and inner portion of the circular aperture of the dilated pupils, and appeared as pearly disks, without movement, attached in this abnormal position. The iris of each eye was tremulous at its outer and inferior segment, on account of its being unsupported by the lens and its ligament at that point. When examination with the ophthalmoscope was made, the periphery of the lens appeared as a black ring,—very much as an air-bubble under the glass cover of a slide looks through the microscope. The fundus could be seen through the lens, but I found it difficult to make out the vessels distinctly: it seemed as though there was haziness of the lenticular substance. Alongside of the lens the fundus could be examined without difficulty by using a +4 lens with the direct examination. The disks seemed pale, but the movement of the eyes, and the necessity of looking through the pupil but not through the lens, made accurate study of the fundus tedious. His vision in the left eye (the strabismic one) was limited to mere perception of light,—or, at least, he was unable to count fingers held before him. The retina seemed entirely amblyopic, for no marked change was seen with the ophthalmoscope. The right eye had an acuity of vision amounting only to $\frac{2}{C}$.

I determined to test him with cataract-glasses, since the eyes, as regarded the visual axes, were evidently in the condition of aphakia. With the left eye nothing was to be done, but with +4½ focal (about 8.50 D) I was enabled to give the right eye vision amounting to $\frac{6}{LXX}$. For reading, +3 focal seemed the best glass, but even then his vision was limited to moderately large print held close to his eye; indeed, he was able to read almost as well without glasses by holding the page within an inch or two of his face and in an oblique direction. He then probably got the rays to pass through the displaced lens. The lens for distance was prescribed when he was first seen.

One month later he returned delighted with

his spectacles, and said he could distinguish the Camden ferry-boats across the river. Examination showed his vision to have increased to $\frac{12}{LXX}$,—twice as much as he saw when spectacles were ordered, at which time, however, the eyes were under the mydriatic effect of atropia.

This is a case of congenital displacement of the lens similar to those usually seen, for the condition is generally double, and the lenses usually occupy the upper and nasal section of the posterior chamber. There is often a hereditary tendency to ectopia lentis, but I do not know that any one of this boy's family has had a similar malformation. The eyes are said to be myopic, as a rule, and we would rather expect them to be imperfectly developed.

No operation would be justifiable in this case, for the left eye is amblyopic, and the right is too useful, now that he wears spectacles, to risk its loss by endeavoring to extract the displaced lens. Abnormally-developed eyes are not apt to bear operations well; and destructive inflammation might follow the performance of extraction.

GUNSHOT WOUND OF KNEE-JOINT AND POPLITEAL VEIN FOLLOWED BY PYÆMIA.

Dr. R. J. Levis exhibited a specimen from a case in which death had occurred from pyæmia due to wound of the popliteal vein. A pistol-ball had entered at the inner side of the ligament of the patella, and, passing through the head of the tibia and obliquely downwards and backwards, had lodged just beneath the integument in the middle of the calf, where it could be easily felt, and was removed by incision. The ball was of large size, weighing one hundred and twenty grains. The patient, a woman, was first seen October 31, 1880. The limb was placed in a fracture-box, and carbolized irrigation applied to the knee. She had with her an infant at the breast, about which she fretted a great deal.

November 3.—Her condition was good up to to-day, when she had a slight rigor. Foot is much swollen and dark. Ordered quinine and iron.

5th.—Irrigation discontinued. General phlebitis was evident, and the leg up to the middle of the thigh was of a dark bluish tinge, while fluctuation of pus in the connective tissue was distinct. Free incisions were made, and a large quantity of pus discharged. Leg placed in fracture-box, in bran dressing.

6th.—Entire limb much swollen and black. Died in the evening.

Autopsy showed metastatic abscesses in the liver, kidney, and spleen, and the lungs were filled with infarctions. Decomposition had set in unusually early. The autopsy showed, moreover, that the ball had traversed the popliteal vein. Phlebitis had commenced at the wound in the vein, the open calibre of which was exposed to the reception of the septic products of inflammation of the surrounding structures.

JOHN B. ROBERTS,
Recorder.

REVIEWS AND BOOK NOTICES.

PHYSIOLOGICAL CHEMISTRY. A Text-Book of the Physiological Chemistry of the Animal Body, including an Account of the Chemical Changes occurring in Disease. By ARTHUR GAMGEE, M.D., F.R.S. Vol. i. London, Macmillan & Co.

We have here the first volume of what is destined to be the most complete work in the English language upon this subject so important to the student of medicine. In the present volume the chemical composition of and the chemical processes relating to the elementary tissues of the body are treated of, the blood, lymph, and chyle being included in that classification. This volume forms a complete and independent work; though it is intended that it shall, within twelve months, be followed by a second volume, in which the chemistry of the chief animal functions will be treated of.

The first chapter, on the "Proteids," is especially valuable, as we have here a satisfactory statement of these compounds so complex and concerning which so little is generally known. On page 16 is a synopsis of the chief proteid bodies, classified according to their most characteristic reactions. About two hundred pages are devoted to blood alone, and of this the parts are first described in detail, then the changes which the blood undergoes in disease discussed, and finally a very full description of the several methods of research involved in a thorough chemical study of the blood under all possible conditions. The completeness of this section may be judged when we mention that it includes an account of the absorption spectra of the blood and the method of observing them and mapping the results, forms of apparatus, too, being given in detail; methods for the quantitative analysis of all the constituents of the blood, both normal and abnormal; the methods of gas-analysis in connection with the analysis of the gases of the blood; and the medico-legal detection of blood-stains and of carbonic oxide in the blood.

On page 406 and the following pages is a most valuable historical sketch of the theories of muscular action from the time of Mayow to that of Liebig and Mayer, and a lucid statement of Hermann's theories, which are the present resting-point of the controversy.

On page 426 is an interesting statement of the chemical dispute as to the existence of protagon, the crystallized brain-principle, and, following this, an account of the decomposition products of lecithin and protagon.

The book gives us most valuable summaries of the present state of discussion among investigators as to important points yet in debate. In addition to the examples just given above, we may be allowed to instance the very interesting account on page 461 and following pages of Kühne's researches upon the "visual purple" of the retina.

The book is well printed and bound, and will, we know, be appreciated. The second volume, if carried through in a similar manner, will make the combined work one indispensable to the student of physiology. S.

HAND-BOOK OF CHEMICAL PHYSIOLOGY AND PATHOLOGY, WITH LECTURES UPON NORMAL AND ABNORMAL URINE. By VICTOR C. VAUGHAN, M.D., Ph.D. Ann Arbor, 1880.

It is essential, in examining this book and passing upon its merits, to remember that it is made up, as indicated by the title, of two distinct parts, and is not a continuous whole. The first part takes up especially the secretions and the more important tissues, and describes the chemical constituents of each, together with the physiology and pathology of the secretions, or even of the more important individual chemical compounds in each secretion or tissue. The chemical descriptions are clear, and when decompositions are spoken of the chemical reactions are written out in all cases where the change is simple enough to be capable of such expression; the sections upon the pathology of the more important chemical compounds are also quite full, and will no doubt be of value to the practical physician. The methods for the qualitative analysis of the several animal fluids are taken largely from Hoppe-Seyler and Gorup-Besanez, to both of whom the author acknowledges his indebtedness.

The second part of the work, to which the plates bound up at the end of the volume belong, is a series of practical schemes of analysis of urine suitable for class instruction (for which it was originally written) or for the guidance of the practical physician. These are also quite full, and are well written. It is a pity that a book containing so much valuable matter has no table of contents and only a trifling index, so that one has to hunt for its best points. It is, moreover, printed upon rather inferior paper, and the binding is more suggestive of old patent-office reports than of a book designed for constant reference in the medical laboratory. S.

MEDICAL DIAGNOSIS. Fifth Edition, Revised. By J. M. DA COSTA, M.D. Philadelphia. J. B. Lippincott & Co., 1881.

In this edition the chief changes are in those parts which treat of diseases of the nervous system and of the blood. Very careful work in these portions has resulted in rendering the chapters very satisfactory, and really enhancing the value of the book. We have only one point to call attention to,—pernicious anæmia. Is it really different from pseudo-leukæmia? It seems to us proven that there are three forms of leukæmia and three forms also of pseudo-leukæmia, viz., splenic, lymphatic, and myelogenic; and we can see no diagnostic difference between acute pernicious anæmias and myelogenic pseudo-leukæmias. Dr. Da Costa's work surely does not in any way clear up the deficiencies. We are glad to learn that a translation of the book into German is being published by Hirschwald. American medical literature in the practical branches bids fair to lead the world: will not some rich man help to maintain scientific pre-eminence by endowing laboratories and professorships so as to enable Americans to work in science?

A TREATISE ON THE PRINCIPLES AND PRACTICE OF MEDICINE. By AUSTIN FLINT, M.D. Fifth Edition, Revised and Largely Rewritten.

The fourth edition of this book was published in 1873, and in the rapid progress of events had fallen behind the science and art which it represents. After careful examination, we find that these deficiencies have been made up, and that in some directions the work in its augmented size more nearly represents the world's knowledge than it ever did. Seven chapters, concerning the general pathology of the solid tissues and of the blood, have been added by Dr. William H. Welch, and are very good. On the whole, the work now seems to us distinctly the best of its kind written by an American, and at least equalling anything in the language. It hardly equals in its thorough satisfactoriness, to our thinking, the great work of Jaccoud, but we have never used any German rival in all respects equalling it. Even Niemeyer is less desirable. When, however, a certain point of excellence is reached, individual opinion is so modified by idiosyncrasies that each man judges by his own needs and fancies, and some may prefer the present volume above all others.

PRACTICAL HISTOLOGY AND PATHOLOGY. By HENEAGE GIBBES, M.B.

The object of this little volume, as stated in the preface, is to lay before the practitioner and student of medicine a few concise and simple methods by which the various tissues of the body may be prepared for examination with the microscope. This object is well accomplished, as the work constitutes a clear and well-written introduction to the technology of the subject. It forms a good guide for beginners, besides containing much matter of interest to more experienced workers. Especially is this last the case in the chapters on staining and double-staining, in which quite a complete account of the action, durability, and practical value of the various sub-

stances used is given, the account including most of the more recent dyes. On the whole, our impressions are decidedly in favor of the book. F. D.

A Manual of the Practice of Medicine and Surgery. By Thomas Bryant, F.R.C.S. Third American from the Third London Edition. By John B. Roberts, A.M., M.D.

We are happy to announce this new edition of the well-known work of Mr. Bryant. From the preface we learn that much of it has been rewritten and eighty-eight new wood-cuts added. Dr. Roberts has also made various additions, chiefly in regard to the work of American surgeons.

GLEANINGS FROM EXCHANGES.

Nephrectomy by Lumbar Section.—At a recent meeting of the Hunterian Society Mr. John Couper exhibited a girl from whom last April he had removed the right kidney, which had been converted into a large cyst filled with pus. The patient's illness had begun in 1879, with pain in the right loin, and loss of flesh and strength. She could not lie on the right side without discomfort. On examination, after her admission to hospital on April 17, the following conditions were noted. The abdomen was not over-distended. A more or less solid mass occupied the right iliac and lumbar regions. There was slight visible fulness to the right of and below the umbilicus, but no marked swelling. The liver dulness commenced at the lower border of the sixth rib in front, and extended nearly to the crest of the ilium. On grasping the loins posteriorly there was pain on the right side only. The inguinal glands were not enlarged. There was slight pitting of the legs anteriorly on pressure. Urine was passed from three to four times daily, and contained about one-third of its volume of pus. By an examination under ether it was found that the ascending colon lay in front of the tumor, that deep-seated fluctuation was present in the latter, that its inner edge reached the middle line, its lower edge to one inch above Poupart's ligament, and its upper edge three-quarters of an inch below the margin of the ribs. The tumor did not extend into the pelvis, was movable, and could be tilted from hand to hand. It did not change position on deep inspiration, and was not connected with the liver. There were no symptoms of cystitis; urine acid. Vagina and uterus healthy. The tumor was obviously the right kidney distended with pus. The chronic character of the symptoms, the absence of any tendency to point, and the presence of pus in a healthy bladder, were all against the diagnosis of perinephritic abscess. As regards the prospect of successful nephrectomy, evidence as to the condition of the other kidney was of vital importance, and here it was noted, 1st, that there had been no vomiting, as if both kidneys were diseased; 2d, that the urine was normal both as to quantity and the percentage of solids contained in it, thus proving that there was no renal insufficiency; 3d, that the amount of albumen present was very small; and, lastly, that the size of the tumor was incompatible with the persistence of any trace of normal secreting structure. The morning temperature was generally normal, and it rarely rose to 102° in the evening. The thoracic organs were healthy, and all these conditions constituted a case exceptionally favorable for nephrectomy, should that operation prove to be necessary. On April 24 the exploratory incision in the right loin was made with the customary precautions against sepsis, the patient being etherized. The section was horizontal, and precisely in the position of that practised in lumbar colotomy. After division of the fascia lumborum, a smooth fluctuating swelling was exposed on the outer border of the quadratus. A trocar plunged into this gave vent to a dark-colored foul-smelling pus in large quantity. Enlarging the opening thus made, and removing the trocar, Mr. Couper passed his forefinger into a loculated sac, obviously the disorganized and dilated kidney. Now arose the question, should this sac simply be drained and allowed to close by granulation, or should it be dissected out? The branching form of the cavity, its enormous extent, and the thick resistant condition of the walls, must have rendered closure by granulation tedious and uncertain. The removal of the kidney was accordingly undertaken. The adhesions of the peritoneum in front were very close, and its separation from the tumor was not effected without a hole being made into the peritoneal cavity. Before this hole could be closed by suture, pus from the kidney contaminated the inner surface of the peritoneum. The ureter was soon reached, tied with strong catgut, and divided. An artery of moderate size below the hilum was ligatured and divided. The main vessels were then tied *en masse* with carbolized silk and divided. The tumor was then quickly detached from its peritoneal connections below the liver and removed. The operation lasted two hours and a quarter, and was throughout all but bloodless. Recovery was uninterrupted. The temperature never reached 102°, and on only three occasions did it exceed 101°. In spite of the fetid character of the pus, the wound did not become septic, and all foul smell was gone in twenty-four hours. For some days after the operation the urine was clouded, and microscopic traces of pus continued to be found in it. These finally disappeared during the third week. The girl left her bed on the thirty-sixth day, and was discharged on the 8th of August. There is still a granulation at the posterior end of the cicatrix, but the girl is rosy and in good health.

Poisoning by Paraffin (Kerosene?).—Mr. Horace Elliott (*Lancet*, vol. ii., 1880, p. 730) reports the case of a child, two years of age, who drank some paraffin. The child was seen about twenty minutes afterwards, and was found to be in a state of semi-collapse, being very pale; the surface of the body was cold and clammy; the pulse small and feeble; the pupils were widely dilated, but acted slightly to the light from a candle. The breath smelt strongly of paraffin. The little patient was dazed and very drowsy, and could only be kept awake with difficulty. Did not cry. The child had vomited slightly before seen, and again soon afterwards. Emetics were administered, which only acted slightly, the vomited matter smelling very strongly of paraffin. The child was not allowed to go to sleep, and about two hours afterwards it began to rally, the surface of the body becoming warmer and the pulse more frequent; the patient cried; there was no diarrhœa. Next morning the child was quite well, the pupils being normal and the breath smelling slightly of paraffin. "From the above notes," says Mr. Elliott, "it will be seen that the symptoms somewhat resembled those of poisoning by belladonna."

Antiseptic Treatment of Empyema.—At a recent meeting of the Manchester Medical Society (*British Med. Jour.*, vol. ii., 1880, p. 744), Dr. Ashby related three cases of empyema treated antiseptically, two of the patients being shown at the meeting. The ages of the patients were two and a half, five, and seven years respectively; all three had a history of five to seven weeks' illness. The treatment consisted in opening the chest under the spray, after the fashion of Hilton's method of opening abscesses,—*i.e.*, making a free incision through the skin of the ninth intercostal space, just in front of the angle of the rib, and pushing a pair of dressing-forceps through the muscles into the pleural cavity, thus avoiding all chance of wounding the diaphragm. Then about half an inch of the ninth rib was excised by a pair of bone-forceps, and a short drainage-tube inserted. The dressings were renewed daily for the first week, but by the end of the first month the discharge had become scanty, and dressing every third or fourth day was sufficient. In two of the cases the discharge had ceased and the wound healed by the end of two months; and in the third in two months and a half. Three months after the operation all three were well. Only one had any deformity of the chest visible to the eye, and that only a slight flattening. The lungs expanded fairly, if not fully.

Treatment of Whooping-Cough in Gas-Works.—A report by M. Henri Roger on this subject made to the Académie de Médecine (*Lancet*, vol. ii., 1880, p. 705) describes the *modus curandi*. The purifying-chamber at the works is a large room, with doors and windows freely open. Each contains twenty-four vessels, holding five cubic metres of depurating substances,—lime and sulphate of iron mixed with sawdust,—through which the gas has to pass. When the workmen are emptying and refilling one of these vessels, the children with whooping-cough are placed around it, and inhale the vapors which escape. They are in an atmosphere containing ammonium sulphide, carbolic acid, and tarry products. The statements made regarding the efficacy of this treatment are the following. M. Commenge records 169 cases in which the treatment was persevered with. In 20 the treatment failed completely, in 48 improvement was obtained, and 101 were cured. M. Bertholle merely states that of 341 cases 122 were improved and 219 were cured. Failures or deaths were not mentioned. M. Roger points out that these results are too good to be satisfactory. He adds that in his opinion the treatment acts only upon one element of whooping-cough,—the catarrh,—and that it is contra-indicated in febrile attacks of the disease and would be positively dangerous in complicated cases. The method is, however, of easy use in some localities and in summer, and seems worthy of further trial in suitable cases, but it is desirable that its effects should be more exactly noted.

Urethral Irrigator. — Mr. Harrison (*British Med. Jour.*, vol. ii., 1880, p. 745) says, "If I am correct in my assumption that the urethra, at and posterior to the bulb (excluding of course the prostate), is the seat of the chronic inflammation we call gleet, how utterly inert our treatment of it must be by injections, as usually and popularly practised!" Mr. Harrison directs his patient to sit on the edge of a chair, and introduce a soft catheter, to which is attached a hand-ball syringe, the other end of which is placed in a tumbler containing the fluid to be injected. He steadies the catheter in the urethra with his left hand (not squeezing the meatus around it), and slowly compresses the ball of the syringe with his right hand, the vessel containing the fluid to be injected being placed by his right side. In this way the patient continues to use the apparatus until the urethra is completely washed out. The fluid, after it has circulated between the walls of the urethra and the catheter, escapes through the meatus and is received into any convenient receptacle. This irrigation is repeated twice or thrice daily, the fluid most suitable to the purpose being fifteen grains of sulphocarbolate of zinc in half a pint of water.

Hysterical Blindness, with Spasmodic Squint.—Dr. W. Manz (*Brit. Med. Jour.*, October, 1880; from *Cbl. f. Prakt. Augenheilk.*) describes the following case. A nervous young lady, of weak constitution, was suddenly attacked, while the subject of headache, with convergent strabismus, especially of the right eye. At the same time a high degree of amblyopia set in, along with concentric narrow-

ing of the field of vision and spasm of accommodation. Ophthalmoscopic examination revealed nothing beyond a doubtful anomaly of formation, probably due to nerve-fibres with a double contour. The patient had almost completely recovered from the condition above described at the end of eight weeks. While it lasted, clonic convulsions occurred several times. A short time after the patient had been dismissed, a relapse occurred, in which, in addition to the previous symptoms, there was transient anæsthesia of the first and second divisions of the fifth nerve. The relapse disappeared at the end of three weeks, and was after a few days succeeded by a third, which lasted four weeks and left slight impairment of visual acuity with asthenopic troubles.

CHOROIDITIS AS A SEQUEL OF RELAPSING FEVER.—Dr. Julius Trompetter (*British Med. Jour.*, October 30, 1880; from *Klin. Monatsbl. für Augenheilk.*) reports that in three hundred and twenty-five cases of relapsing fever in Breslau, twenty-one cases of choroiditis were observed. They were mostly of the acute form. On admission to hospital, the patients mostly presented the characters of well-marked choroiditis in the form of cyclitis. Very frequently hypopion appeared, in the absence of inflammatory phenomena on the part of the iris. Turbidity of the vitreous humor was ascertained in all the cases, and the visual acuity was always considerably impaired at the commencement of the illness. The field of vision showed a limitation of the periphery in all directions. The course of the choroiditis was in general favorable: its average duration was from a month to six weeks. In two cases both eyes were affected. Dr. Trompetter believes that the affections of the eye in relapsing fever are due to embolism arising from partial necrosis and abscess of the spleen.

DECALCIFIED BONE DRAINAGE-TUBES.—Surgeon Shirley Deakin writes to the *Lancet* (vol. ii., 1880, p. 692) suggesting the decalcified long bones of poultry and small birds as appropriate for drainage-tubes in localities where these cannot conveniently be procured. The bones, well boiled to free them from the soft parts, are soaked for about ten hours in a mixture of one part of hydrochloric acid and two parts of water. Immersed for this time, they become sufficiently soft and flexible for use and to be cut off with ordinary scissors. The ends are now cut off and the medullary cavity cleaned out with a wire. The bone-tubes should then be boiled in a five-per-cent. solution of carbolic acid to which some borax has been added. The tubes are kept in a five-per-cent. solution of carbolic oil.

A SEVERE CASE OF FACIAL NEURALGIA CURED BY A NEW SURGICAL OPERATION.—Dr. Augustus Brown (*British Med. Jour.*, vol. ii., 1880, p. 741), in a case of severe and intractable facial neuralgia, made an incision along the lower border of the jaw and dissected up a flap till he reached the mental foramen. He then ran into the foramen a red-hot steel wire for a quarter of an inch or so, and thoroughly destroyed the nerve. On withdrawing the wire the artery bled considerably, so that he was obliged to plug the foramen. This caused suppuration and some delay in the healing of the wound, which, however, did heal kindly, and the patient from that time has been entirely free from pain and restored to health.

DANGER OF INJECTIONS OF TINCTURE OF IRON IN NÆVUS.—A correspondent of the *British Medical Journal* says, "A child, ten months old, was brought with a small nævus on the right side of its head. I injected five drops of tincture of perchloride of iron with two drops of water. In about a minute the child's face was of a peculiar pea-green color, with black stripes,—the veins. The tip of the syringe had entered a small vein. After four hours' hard work, and with the greatest care, the child's life was saved. Since then I have never used injections for the cure of nævi."

BROMIDROSIS.—Mr. J. W. Martin (*British Med. Jour.*) recommends the following:

℞ Plumbi acetatis, ʒi;
Aceti destillati, fʒj;
Alcoholis, fʒij;
Aquæ ad Oj.—M.

To be used, after washing the feet with soap and water, night and morning.

TREATMENT OF PROLAPSUS ANI BY HYPODERMIC INJECTIONS OF STRYCHNIA.—Dr. Leonard Weber (*New York Medical Record*, 1880, p. 682) inserts the needle about three-fourths of an inch from the anus, and, directing it upward and parallel to the gut, injects one-twenty-fourth to one-twelfth grain of the remedy, repeating the injection in forty-eight hours.

Three cases were thus treated successfully. In one, a man of forty-five, six injections, of one-twelfth of a grain each, were necessary. In a boy four years old, with a prolapse of a year's duration, four injections, of one-twenty-fourth of a grain each, sufficed for a permanent cure. In a girl of six a similar number of injections cured completely.

SECONDARY EPITHELIOMA OF THE LUNG.—At a recent meeting of the Pathological Society, Mr. Goodlee showed one case where there were numerous tumors in the lungs consecutive to epithelioma of the tongue, and a second case where there was an epitheliomatous nodule of the lung consecutive to epithelioma of the bladder. The epitheliomatous nature of the growth was more marked in the latter than in the former case. In this, however, there was typical secondary epithelioma in the kidneys and supra-renal capsules. The President said he had removed a man's tongue for epithelioma. He had remained well for two years, and had then died with secondary epithelioma of the lung.

THE treatment of *acne rosacea*, or "*whisky-*

nose," by electrolysis is advocated by Dr. G. S. Mitchell (*Cincinnati Lancet and Clinic*). He reports seven cases cured, or almost so, by this method. He uses fifteen or twenty cells (galvano-faradic cabinet battery). One or both poles of the battery are armed with needle-electrodes, and these are introduced here and there into the dilated vessels. The needles are not allowed to remain more than half a minute in one place, the treatment lasting about five minutes. From eight to twelve séances were sufficient to cure the patients. The operation is painful, though not so much so as to require an anæsthetic.

JOINT-DISEASE IN LOCOMOTOR ATAXIA.—At a recent meeting of the Pathological Society (*British Med. Jour.*, vol. ii., 1880, p. 743) Dr. Payne showed a man who had suffered from syphilis and now presented well-marked symptoms of locomotor ataxia. He had considerably improved under antisyphilitic treatment, but had recently developed hydrarthrosis in the left knee-joint. Gastric symptoms were absent till a week ago, when he had an attack of vomiting, without obvious cause, bringing up clear fluid. Dr. Buzzard had ascertained from the patient that he had been liable for the last three or four years to attacks of retching and vomiting. He had previously called attention to the frequent association of joint-disease with gastric attacks in locomotor ataxia; and since that time he had seen three cases of joint-disease in ataxic patients, two of whom presented also gastric symptoms. He thought the attacks of nausea and vomiting were of some importance from this point of view.

GELOSITIS WITH SUPPURATION IN A SYPHILITIC INFANT.—Dr. Lees, at the same meeting, showed a hereditarily syphilitic baby in whom the left elbow and right knee-joint had become much enlarged, the child being then six weeks old. Both joints had suppurated and had opened spontaneously. The left knee-joint subsequently suppurated and had been aspirated. The child had recovered under mercurial treatment, with a fair degree of movement in all the joints. Noteworthy points were: 1, the multiplicity of the affection; 2, the early age at which the bone disease had occurred; 3, the good recovery under mercurial treatment.

MISCELLANY.

CENTENARIANS.—Dr. J. C. Taché, a prominent official in the Canadian government, made centenarianism a study at the time of the taking of the Dominion census in 1871, submitting the 82 cases reported by the enumerators to the Abbé Tanguay, who obtained from the parish priests and notaries over 1000 acts of registration. Of these 82 reputed centenarians, no less than 73 were proved to be under five score. Of 31 claiming to be 100 years old, 28 were shown to range from 79 to 99; of 9 persons said to be 101, the oldest was found to be 99; of 9 said to be 102, the oldest was 89; of 4 claiming to be 103, the oldest was 95; of 4 claiming to be 104, the oldest was 99; of 7 claiming to be 105, the oldest was 97; of 3 claiming to be 106, the oldest was 98; of 3 claiming to be 108, the oldest was 95; of 3 claiming to be 110, the oldest was 98; while the old inhabitant of 112 was reduced to 81, the claimant of 112 to 91, and the patriarchal François Torgues's 120 years dwindled to precisely 90. There remained 9 admitted cases: three persons were found to be 100 years old, one was 101, one was 102, and two others were 103, while Rosalie Lizotte's claim to 109 was passed, and to Baptiste Joubert's 105 years 8 were added. Of course there is a presumption against two persons having reached the ages of 109 and 113, when of the other seven admitted centenarians only two lived to be 103, and it is quite possible that there have been errors in the records, such as would have arisen from the death of a child at the age of 6 or 8, and the naming of the next one born after it, when almost inevitably the younger child would be given the elder one's age by a searcher coming a century afterwards. But there is a *primâ facie* case made out, and the fact is well known that the French Canadians are not less remarkable for their vitality than for their fertility. It is to be hoped that General Francis A. Walker may make as rigid inquisition as is possible into the many hundred cases of centenarianism which will surely be recorded in the census reports, or, if this is not possible, will at least publish a list of the cases, and so facilitate the work of independent investigators.—*The American*, 1880, p. 77.

EIGHTY-THREE GRAINS OF OPIUM *vs.* ONE-QUARTER OF A GRAIN OF ATROPIA.—Dr. J. W. Bryant reports, in the *Virginia Medical Monthly*, a case of opium-poisoning successfully treated with gr. ¼ of atropia. The patient, a man, had taken ℥iiss of laudanum on an empty stomach. Two hours passed before anything was done for his relief. Emesis could not be produced, and, as there was no stomach-pump, Dr. Bryant had to rely entirely on atropia. One-fourth of a grain was given hypodermically in four hours in six doses. When it was given, the man had marked symptoms of opium-narcosis,—lightly-contracted pupil, slow and labored respiration, slow and weak pulse. The first perceptible effect of the atropia was after the second dose, when the pupil began to dilate slowly; it was not fully dilated until after the sixth dose. The pulse continued to rise until from 55 it was 125. There was no effect upon the respiratory centres. The galvanic battery was used for a time with no very striking result. At 1 A.M. the patient was left, the physicians not knowing whether he would live or die. Next morning he was awake and con-

scious, but in the condition of a man who had been on a "big spree." Some delirium appeared the next day, but the patient was soon in good condition again. His bowels were not constipated.—*New York Medical Record.*

How the Pennsylvania Hospital impresses Foreigners.—The *Lancet* for October 23 contains an article from a travelling correspondent in Philadelphia, in which he gives his impressions of the Pennsylvania Hospital. He admires the telephonic communication with each member of the staff and the police headquarters. The excellence of ventilation he finds among the most remarkable features of the hospital. The bedstead carriage and Morton's ward dressing-carriage also struck him favorably. He takes exception to the resident physicians' rooms, one medium-sized apartment being scarcely sufficient accommodation, in his opinion, as the common bedroom and sitting-room of two officers. What he would have said to the state of affairs ten years ago, when the resident's room was made to do duty as a consultation- and gossip-room for the staff, and when fixed wash-stands, in direct and untrapped connection with the sewer, poured their miasma into this same apartment, we cannot say. It was a good room to get typhoid in, like that of the landlady in the old verses:

"In this excellent room died three people of fashion."

We fear the resident physician who acted as guide to the English visitor was a wicked University wag; for, says the correspondent, "I was assured that at Jefferson College, which is one of the leading medical schools in this country, a man might take his degree in medicine and go forth and practise his profession *without having ever seen a case.*"

New Remedy for Epilepsy.—Not an over-nice remedy is magpie dust, which no less a personage than the Princess Bismarck apparently deems an infallible specific for epilepsy, since, no longer ago than January of last year the president of the Eckenfoerder Shooting Club addressed the following circular to the members of that association:

"Her Highness Princess Bismarck wishes to receive before the 18th instant as many magpies as possible, from the burned remains of which an anti-epileptic powder may be manipulated. I permit myself, therefore, high- and well-born sir, to entreat that you will forthwith shoot as many magpies as you can in your preserves, and forward the same to the Chief Forester Lange, at Friedrichsruh or hither, without paying for their carriage, down to the 18th of this month."

Vol. ix. ("Diseases of the Liver and Portal Vein") of Ziemssen's "Cyclopædia of the Practice of Medicine" has been received. It completes the American reprint of this great work. There is still another volume due in Germany. The time of its appearance is so uncertain that the publishers think it wisest to omit it from the American series, and announce that, upon the issue in Germany of the work on "Diseases of the Skin," which will there form a part of Ziemssen's Cyclopædia, they will at once have it translated and publish it here as an *independent volume; and, further, they will present a copy, tastefully and strongly bound in muslin*, to every subscriber to Ziemssen's Cyclopædia who has completed his set by that time.

Medical Journals of the World.—Of these, France and her colonies possess 147, of which 95 are published in Paris alone. Germany has 129; Austria, 54; Great Britain, 69; Italy, 51; Belgium, 28; Spain, 26; Russia, 26; Holland, 16; Switzerland, 10; Norway and Sweden, 9; Denmark, 5; Portugal, 4; Turkey, 2; Greece, 1. In America 183 journals are said to be published, but this must be an under-estimate. Asia is supplied with 15, while Oceanica boasts 2, which should have a wide circulation. The entire number of medical journals published the world over is 785, most of which live by preying upon each other directly or by bolting the half-digested items obtained at third-hand from the journal in which they were originally "extracted."

Odium Scientificum.—The calm, cold atmosphere of scientific discussion does not appear to prevent that heated state of feeling formerly supposed to be the peculiar weakness of theologians. At a recent meeting of the Académie de Médecine, Prof. Pasteur's course in keeping secret one of his scientific discoveries was animadverted upon by Prof. Guerin, whereupon Pasteur said, cuttingly, "When, in the name of clinical principles, a man has proposed to aspire pus to the surface of wounds by means of an india-rubber cup, some tubes, and a pneumatic pump, he is capable of anything." These personalities nearly ended in a duel, the rumor of which, it is said (owing to the fact that one of the would-be combatants is nearly an octogenarian, and the other hemiplegic), caused some hilarity in the Academy.

Borax in Hoarseness.—This salt has been employed with advantage in cases of hoarseness and aphonia occurring suddenly from the action of cold. The remedy is recommended to singers and orators whose voices suddenly become lost, but which by these means can be recovered almost instantly. A little piece of borax, the size of a pea, is to be slowly dissolved in the mouth ten minutes before singing or speaking. The remedy provokes an abundant secretion of saliva, which moistens the mouth and throat. This local action of the borax should be aided by an equal dose of nitrate of potassium, taken in warm solution before going to bed.—*La France Médicale.*

Poisoning by Chlorate of Potassium.—The Marseilles *Médical* relates a case of poisoning by chlorate of potassium. An el-

derly man took, in mistake for Epsom salts, thirty-five grammes of chlorate of potassium. Death, which followed in seven hours after the ingestion of the salt, was preceded by the following symptoms: vomiting, colic, and diarrhœa, general weakness and rigidity of the limbs. After death the skin of the dorsal and lumbar regions presented a slate-colored appearance.

FAILURE OF WICKERSHEIMER'S "PRESERVATIVE FLUID."—The absolute failure of Wickersheimer's solution, so widely quoted as the best preservative of anatomical subjects, appears to be settled. The solution of acetate of alumina is said to be much better, and deserves a thorough test. Burow used a concentrated solution as an injection with such success that after two weeks two cadavers (children) showed no evidences of putrefaction.

GERMAN EYE AND EAR INFIRMARY.—In the year 1880 there were gratuitously treated in the Dispensary of the German Eye and Ear Infirmary (Dr. M. Landesberg, surgeon-in-charge), 441 North Fifth Street, 1190 patients, of which number 829 were for eye diseases and 361 for ear diseases. The number of important operations performed in the institute was 111; of minor ones, 153.

WHAT IS FAME?—Prof. Laboulbène, in a long and interesting lecture on the history of medical journalism, gives the following list of the leading medical periodicals published in America: *The American Journal, Boston Medical and Surgical Journal,* the reviews and medical journals of Cincinnati, Indiana (!), New York, etc. etc.

ACCORDING to Mr. D. G. Crain, United States consul at Milan, from 230,000 to 260,000 pounds of quinine are produced in the world yearly, of which 45,000 are manufactured in Italy.

NOTES AND QUERIES.

ACCEPTANCE BY DR. WILLIAM PEPPER OF THE OFFICE OF PROVOST OF THE UNIVERSITY OF PENNSYLVANIA.

To HON. JOHN WELSH, CHAIRMAN:

DEAR SIR,—I had the honor of receiving to-day a subcommittee, composed of Messrs. Rogers, Merrick, and Mitchell, who informed me of my unanimous election as Provost of the University of Pennsylvania.

They informed me at the same time that the Board of Trustees had made certain modifications in the duties and powers of the Provost, and had also enlarged the disciplinary and supervisory functions of the respective faculties.

While rejoicing at what appears a marked improvement in the organization of the University, I am highly gratified at finding that these changes render it possible for me, while continuing to hold my chair in the medical department, and to pursue the practice of my profession, to accept the important post to which I have been elected.

I shall esteem it the highest honor and privilege to be able to serve the University in this capacity; and I earnestly trust that, with the cordial co-operation of the Board of Trustees and of the various faculties, the general welfare of the institution and the efficiency of its administration may continue unabated.

I have the honor of remaining

Your obedient servant,

WILLIAM PEPPER.

OFFICE OF THE PUBLIC PRINTER,
WASHINGTON, D.C., January 19, 1881.

EDITOR OF THE *Philadelphia Medical Times:*

SIR,—This office is almost daily in receipt of letters from medical men throughout the country asking where they can obtain copies of the "Medical and Surgical History of the War."

To those of the fraternity interested I take this method of informing them that a bill has recently been introduced in Congress which authorizes the Public Printer to reprint from the stereotype plates an edition of fifty thousand copies of each of the four volumes heretofore issued from the Government Printing-Office. The fifth volume is now going through the press. Should the bill become a law, these books will be for gratuitous distribution by Members of Congress. Consequently, those who make timely application can, no doubt, be accommodated.

By giving the above communication a place in your valuable journal you will, I think, confer a favor on the faculty generally.

Yours respectfully,

A. F. CHILDS,
Chief Clerk.

WANTED.

HUMAN EMBRYOS, from the second to the fourth month of development, for microscopical study of developing teeth. Address DR. E. T. DARBY,
No. 1513 Walnut Street,
Philadelphia, Pa.

January 19, 1881.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM JANUARY 9 TO JANUARY 22, 1881.

BAILY, J. C., MAJOR AND SURGEON.—His leave of absence granted him in S. O. 188, December 13, 1880, Military Division of the Pacific and Department of California, extended one month. S. O. 13, A. G. O., January 18, 1881.

COUES, E., CAPTAIN AND ASSISTANT-SURGEON.—Having reported in person, is assigned to temporary duty in the office of the Medical Director of the Department. S. O. 1, Department of Arizona, January 3, 1881.

MEACHAM, F., CAPTAIN AND ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Niagara, N.Y., during absence on leave of Assistant-Surgeon Price. S. O. 6, Department of the East, January 10, 1881.

GIRARD, J. B., CAPTAIN AND ASSISTANT-SURGEON.—To be relieved from duty in Department of Texas, by Commanding General thereof, on receipt of this order, and then to report in person to the Commanding General, Department of Arizona, for assignment to duty. S. O. 14, A. G. O., January 19, 1881.

TAYLOR, B. D., CAPTAIN AND ASSISTANT-SURGEON.—To be relieved from duty in Department of the East, by Commanding General thereof, on receipt of this order, and then to report in person to Commanding General, Department of Texas, for assignment to duty. S. O. 14, c. s., A. G. O.

PRICE, C. E., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for one month and ten days, to take effect on arrival of Assistant-Surgeon Meacham at Fort Niagara, N.Y. S. O. 2, Military Division of the Atlantic, January 10, 1881.

COMEGYS, E. T., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for four months on Surgeon's certificate of disability. S. O. 4, A. G. O., January 7, 1881.

BURTON, H. G., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Now awaiting orders at Boston, Mass. To report in person to the Commanding General, Department of the East, for assignment to temporary duty. S. O. 7, A. G. O., January 11, 1881.

PHILADELPHIA, FEBRUARY 12, 1881.

ORIGINAL LECTURES.

ABSTRACT OF A CLINICAL LECTURE ON A CASE OF NEURITIS OF THE BRACHIAL PLEXUS BELIEVED TO BE DUE TO MEDIASTINAL CARCINOMA.

Delivered at the University Hospital, January 22, 1881,

BY H. C. WOOD, M.D.,

Clinical Professor of Nervous Diseases in the University of Pennsylvania, etc.

Reported by Dr. CHARLES K. MILLS, Chief of Nervous Clinic.

GENTLEMEN,—This man comes to us complaining of pain at the root of the neck, extending into the right arm and associated with great tenderness. He states that he has had epilepsy for nearly forty years; but his intelligence seems to have been in no wise affected thereby. He is very bright and shrewd in his answers, denies all loss of memory, and offers no history of headache, vertigo, or other evidence of gross cerebral disease. His present illness he dates back to last August, when the pain, of which he now complains so much, commenced, and, to use his own words, the "cords of his neck began to draw down." The pain since it set in has steadily increased; it is persistent, with exacerbations, and frequently at night entirely banishes sleep. At the same time the unfortunate sufferer has gradually been compelled to assume the posture which you now see. His head and body are bent far forward, so as to give his spine a marked curvature. If he attempts to straighten himself, or if you try to pull him backward to an erect position, he complains of great pain at the root of the neck. He crouches in this ungainly position, not from any paralysis of the muscles of the back, but because of the pain which he suffers if he tries to assume any other posture. Even at night he cannot stretch himself out at full length: in fact, he usually sleeps propped half up in bed or in an arm-chair. His shoulders and upper chest appear to be drawn downward and forward by muscular spasm.

When I touch him you observe evidence of great hyperæsthesia over the right shoulder, right arm, and right side of the neck and chest. He shrinks in alarm from the slightest touch. The man complains of no shortness of breath; but, as I look at him stripped, his respiratory movements are evidently hurried, and on counting I find them twenty-eight a minute. On looking further for evidence of disturbed breathing, you see that inspiration is distinctly longer than expiration, and that the right supra-clavicular space is sunk in much more than the same space on the left side, especially during a full inspiration; also notice that a distinct line or groove of depression or sinking is seen between the lower ribs on the right side, this not being present on the left. Further, if you watch a moment, you will no doubt agree with me that the play of the spaces between the ribs is much freer on the left than on the right side: even during forced inspiration the left intercostal spaces do not fill out.

Passing from the chest, your attention must have been at first sight attracted to the tumor which he has in his neck. It is without doubt an enlargement of the thyroid body, as it is not affected by respiration, but is controlled by the movements of the larynx. It is very tender to pressure. Searching farther, I find several other hard bodies deeply placed in the neck. They are evidently glandular enlargements. This thyroid tumor has been present for years, but it was small until last August, since which time it has grown steadily. The enlarged glands have probably recently appeared; but we can get no distinct information upon this point.

This man, gentlemen, has been before a number of physicians of this State without their being able to tell him what his disease was,—at least, so he states,—and comes to-day for an opinion as to his ailments. Of course he has epilepsy; but this does not seem in any way connected with his present illness,—it is of too long standing, and has given rise to too little evidence of severe cerebral implication, whilst the present attack is substantially acute. There seems to be a general neuritis of the whole brachial plexus, as is indicated by the hyperæsthesia and shooting pains. You may say these are centric, due to a cervical pachymeningitis; but not so, gentlemen. A cervical pachymeningitis could hardly be so absolutely one-sided as the symptoms here necessitate, or so accurately confined to the region of the brachial plexus. More-

over, the nerve-trunks are everywhere exceedingly tender; and this indicates a neuritic rather than a centric hyperæsthesia. Further, cervical pachymeningitis could not account for the chest-symptoms.

You will say, Why is it not aneurism? There are no physical signs of aneurism discoverable; the pulses on the two sides are uniform both in the radials and in the carotids; there are no evidences of disturbed circulation in the neck; it is not conceivable that an aneurism could get high enough in the neck to implicate so seriously the brachial plexus and not reveal itself; an aneurism would not cause enlargement of the cervical glands. These, stated very briefly, are the reasons why an aneurismal theory is not, to my thinking, tenable.

The man attributes his trouble to the tumor on the neck. Pressure upon it causes shooting pains throughout the whole affected region; but pressure on the arm or supra-clavicular space, or even on the front of the chest, will do the same thing: so that this signifies nothing. The neck tumor feels like a cystic degeneration of the thyroid gland; but I do not believe that the whole of this patient's disease is in the thyroid gland. The respiratory symptoms are pressure-symptoms, but they are not the manifestations of laryngeal pressure. You have here no hoarseness, no loss or change of voice. Moreover, the larynx is quiet, and does not make the irregular movements which are so generally connected with laryngeal obstruction. Besides, the contraction in the intercostal spaces and the sinking in of the base of the chest are very much more marked on the right side than on the left. The disease of the cervical glands, likewise, is not sufficient to account for the symptoms. Pressure is exerted on parts too low in the chest to be affected by cervical enlargements.

The respiratory symptoms are so one-sided that it seems to me they must be due to pressure upon the right bronchi. It is strongly probable that we have here a case of mediastinal tumor.

In the mediastinum, as you know, are many glands. The condition of the cervical gland would indicate that these are diseased. The rapid development of the condition would indicate something more than lymphadenoma: this is confirmed by the severity of the neuritis. There is not evidence enough of pressure to explain altogether the involvement of the brachial plexus. It would seem that these nerves are surrounded by something which not merely presses but, much more, irritates them. Mediastinal tumors are very frequently sarcomatous; and it is most likely that the man has extensive sarcomatous or carcinomatous degeneration of the mediastinal glands, giving origin to a similar disease of the cervical glands and causing neuritis of the brachial plexus.

Such being our theory of the case, the prognosis is, of course, bad: little can be done, only that his sufferings may be alleviated by the free use of narcotics. I have, however, given so unfavorable an opinion that the man is anxious to leave the hospital for his home in the centre of the State.

ORIGINAL COMMUNICATIONS.

THE PROFESSIONAL RELATIONS BETWEEN THE PHYSICIAN AND THE DRUGGIST.

Read before the Philadelphia County Medical Society, November 24, 1880,

BY GEO. B. H. SWAYZE, M.D.

MR. PRESIDENT AND FELLOW-MEMBERS,—By your indulgence I desire for a short time to join you in some consideration of one of the most important and universally-felt interests of our profession. While the subject is not new, every observing, thoughtful practitioner of medicine must often realize that the problem of the medical and pharmaceutical relations deserves renewed and vigilant consideration, in order that some reformative means may be devised, through which evils of omission and evils of commission pertaining to the professional relations between physician and druggist may be corrected. To the great mass of physicians the practice of medicine has its business aspects as well as its more strictly professional province. In the experience of a large proportion of the members of our humane profession it is doubtless often a question which of these relations of professional life, business or medicinal, necessarily assumes the more vital consequence. The professional prosperity of the physician, and, as society has learned to gauge civil and social values, often the professional prestige of the physician, depend not only

on his educational proficiency, or on his opportunity of serving the needs of an ever-needy public, but also on his ability to secure adequate and reasonable compensation for his devotion to a high and worthy calling. In every other profession and avocation this business feature of their work has ever been more definitely and rationally recognized than in the medical. I believe that more than one physician has repeatedly found reason to feel that the ideal humanitarian embodiment of the practice of medicine has been so fostered that many people have educated themselves to the sentiment that *doctors are conveniences without rights*, whenever the latter conflict with the selfishness and caprice of those who use them.

In taking a comprehensive glance at the inter-professional domain of physicians and pharmacists, we perceive that the office of physician is peculiarly that of discerning the nature of diseases, of deciding what are the therapeutical indications of their treatment, and either dispensing or directing, orally or by prescription, what remedies he considers proper for their relief; while, professionally, it is the office of the pharmacist to prepare, preserve, and compound the remedies needed by the physician in the treatment of disordered conditions of the human system.

In the earlier days of the healing art, before it became the fashion for the medical practitioner to delegate to another class of business-men almost the exclusive management of the therapeutics of medical practice, physicians furnished themselves with the remedies actually needed, kept under their own control the knowledge and prestige of their art, attended patients at less unnecessary expense than attaches to the modern mode, were held in high personal and public appreciation, enjoyed lucrative incomes, and were everywhere recognized as influential and honored factors of society.

As the apothecary advanced from the obscurity of pharmaceutical chaos, and the medical practitioner reached to him the hand of friendship and professional support, the physician did not foresee that, through the system of prescription-writing and the sending of patrons to drug-stores for all needed remedies, he would be placing both his professional knowledge and his business interests, day by day, year by year, continuously into the hands of the druggist, and that through these the opportunities, influence, and importance of the druggist would so rapidly augment that said druggist would soon become the formidable business rival of the physician in nearly every practical sense, while the professional consequence and prosperity of the physician *must* proportionally wane.

Before proceeding further, Mr. President, I beg to disclaim any intention of reproach or invidious purpose in my references to what strike me as radical defects in the ethics adopted in practice by pharmacists in their relations towards physicians. I lay nothing at the personal door of any particular druggist, but aim solely to reach some analysis of the principles on which our mutual relations are conducted, and get some periscope of the ground lying between the individual provinces of physician and druggist. And in this connection let me premise that as businessmen the generality of druggists excel the generality of physicians. They are enterprising gentlemen, who guard and exalt their opportunities with pious, almost Spartan, fidelity, who make their profession the *medium* of *business*, and neglect no means that come within their reach to advance their pecuniary interests. In nearly all cases of illness attended by the physician the druggist gets hold of the cash end of the account, while the doctor is left to console himself with the trust end. Ostensibly the druggist is the aid of the physician. He keeps in stock an extensive variety of remedials from which the physician is to draw supplies for patients, usually on written instructions. The druggist solicits the confidence and aid of physicians, and expects to be sustained through the patronage of their clients. With his eye on the "main chance," the druggist makes it a rule to "never turn a customer away," lest he carry his money to somebody else. Therefore, if a physician prescribes for a case, and his prescription proves decidedly successful, instead of that physician reaping his legitimate, substantial reward for his skill, the druggist takes it instead, often for the remainder of his life. The prescription, being a written instruction or direction for temporary use only, is placed on file by the druggist for future reference, and as often and as long as the refilling of that prescription is applied for by the party for whom it was originally intended, or his

friends and neighbors, it is put up without any reference to the prescriber's knowledge, wishes, or interests.

Perceiving that the druggist is the recipient of the unbounded confidence and daily patronage of the physician, and finding the druggist such an accommodating substitute for the physician in mild cases when the patient is not absolutely bed-fast, and sometimes when he or she is so, it comes to pass that there is carried on a continuous undercurrent of medical practice over the counter by the druggist, either with or without the aid of the physician's prescriptions on file.

Sundry capitalists and patent-medicine speculators aim to create a demand for their wares by turgid praise and misleading puffery. The powers of the press are invoked to carry the glad tidings to all the afflicted. Patent-medicine almanacs and proprietary-nostrum circulars bearing the imprint of names and business address of druggists of established reputation in the neighborhood, with their gorgeous invitations to come and be healed, are pushed into every house. The obliging druggist puts the advertised articles into stock in unending variety and attraction. He has received the compliment of a thorough advertising gratis, and his illuminated windows, gleaming shelves, and chaste marble counters bristle with these formidable and injurious substitutes for legitimate medical practice. Instead of co-operating with the conscientious, well-meaning, deserving physician by holding the local field for legitimate prescribing, the druggist becomes the introducing and selling agent of these astute nostrum-speculators for a percentage margin; and by the dispensation of such nostrums, whether by gift or by sale, the druggist constitutes himself the practitioner of quackery, virtually assumes the treatment of the innumerable diseases for which the bottle-wrappers effusively recommend the contents, and thus yet further curtails the physician's field of professional usefulness and support. It is apparent that patent-nostrum speculators depend on druggists for their success in coining millions of dollars from the means of the always gullible public, while the regular physician is often left to plod in penury through a life of disappointment, hardships, and privation.

If it is the moral duty of the enlightened physician to protect his patrons and the public from the injuriousness of patent nostrums, why is it not the moral duty of the enlightened druggist to do so also? Is it not because his business principle forbids him from ever turning a customer away, lest he go to somebody else? Is it not because the dollar is the prime consideration? Is it not because he is so thoroughly wedging himself between the physician and the public that the physician must take the lamb's share while the druggist appropriates the lion's share of general medical practice?

It is the policy of patent-medicine advertisers to prejudice the minds of the unstable against the employment of physicians in the diseases for which they offer panaceas. They affirm that, if their nostrum does not give relief, it is useless to run up a bill with a doctor, as the article has been known to cure thousands of cases that had been given up by the doctors; for the evidence of which they refer people to the druggists who handle their wares. These wily sharks thus hold out their delectable bait for the credulous, the anxious, the venturesome, the constitutionally infirm, who grasp at every straw tossed in their way by the capricious winds of chance or *finesse*, and go down amid the confusion and effusion of their deceptions. Without doubt it is the semi-professional prestige given these nostrums by their pharmaceutically educated agents, our respectable and influential druggists, who display the flaming show-cards, display the miraculous wares, display their overwhelming recommendations, that keeps in daring vigor the impetus of their sale among the people, resulting in increasing injury to the public, tampering with the opportunities for relieving and restoring impaired health, and aggressively encroaching on the professional province of the regular physician.

A flagrant injustice is done physicians by druggists who, without being so authorized by the prescriber, frequently and indefinitely renew prescriptions intended by the physician for temporary employment only, and often making them up for persons or families other than the one for whom they were designed. This disloyalty to the confidence and purpose of the physician practically cuts off a large measure of the just support of the physician by placing the druggist in the field as the prescriber and personal substitute of the

medical practitioner, and presenting the impolitic virtue of surreptitiously appropriating the doctor's brain and recipe to guillotine the doctor's income!

There is no doubt that the abuses of unauthorized renewals seriously endanger the welfare of patients by the prolonged use of potent remedies, as calomel, nux vomica, the iodides and bromides, chloral, morphia, opium, and alcohol.

As excuse for the commission of this wrong it was recently urged by representative pharmacists in conference with a number of physicians that physicians do themselves the injustice in great measure by not putting upon their prescription-blanks, "*Not to be renewed*"; and, further, having procured the prescription from the doctor, it belonged to the patient to use as he pleased. That these fallacies should be offered as a "scape-goat" it is natural to expect. In the first place, every intelligent druggist *knows* what was the *intent* and *purpose* of the physician when he wrote the prescription that is brought to the apothecary to be filled, and every such druggist knows that his disregard of the intent and purpose of that physician is a breach of good faith and a professional as well as a business injustice towards the prescriber: it is *not* doing to others as you would that others should do to you. A prescription is simply a *written direction* to the druggist stating *what* the physician desires shall be *furnished* the patient *at that time*, and embracing the *directions* as to *how* the remedy shall be taken. The *prescription*, or *note of instructions*, together with the *functions* performed by the *apothecary*, constitutes simply a *substitute* for the *dispensing of the indicated remedial by the physician's own hands*. In considering his cases the physician's *knowledge*, *experience*, and *judgment* are brought into requisition. The *patient* receives the benefit of *these* in his *conclusions and advice*. If he charges a fee, it is for his *professional service*. His *direction* as to what the druggist shall compound for the case is an *incidental matter*. This use of the prescription is guaranteed the patient for once filling, and does not confer on the patient or the druggist the right to *hazard the renewals of that prescription indefinitely and promiscuously*. The existence of such rights is a misconception, even of statute, if there be any such. Law is the guardian of the public welfare: its spirit and purpose mean protection. It does not give man the right to abuse or injure either himself or others. The law recognizes the sovereignty of *purpose*. The spirit of the purpose is recognized as defining the merits of the act. *The only problem to be grasped in defining the proprietorship of the prescription is the purpose of the prescriber.* If the physician has no moral right to jeopardize the welfare of a patient or the public, common sense must teach that he would not so stultify himself as to extend to patient or druggist a *carte blanche* privilege of doing what the doctor himself has no right to do. It is an astounding doctrine, fostered by pharmacists, that the will and purpose of the prescriber are to be subverted by the rashness of the patient, the stealth and inconsiderateness of persons who venture to use prescriptions compounded for other people, and the business policy of druggists, who habitually thus expand pharmacy into a medical quack practice according to their constant and increasing opportunities. As physicians it is just that we ask ourselves this great question: Are our prescriptions, our professional knowledge and experience, and the business prestige pertaining to these, to be trucked out at will by those whose opportunities make them custodians of our written instructions relative to cases to which we are called? *The legality of the proprietorship immunities of our written prescriptions or instructions may be very promptly settled by our suspension of the fashion of issuing them.* There must certainly be some method by which the medical province, the public welfare, the professional dignity, may be protected.

In the absence of statistics, I venture the assertion that druggists conduct one-half of the medical practice of the day through the continuous and broadcast dispensation of patent and proprietary medicines, by renewals of physicians' prescriptions, and by other ventures at prescribing for persons over the counter on some general statement of symptoms or complaint by the applicant, either for himself or other member of the family, or for some friend.

Thoughtlessly physicians have for years been giving out so much professional rope to pharmacists and the public, and in the mean time pharmacists have so industriously and energetically wedged themselves in between the "dear public" and

the professional province of the physician, that they are rapidly getting into shape to monopolize the field of medical practice. Already representative druggists claim that the pharmacist has the first ear of the public, and that upon his recommendation it depends who shall find general employment in the community. From the fact that druggists manipulate the prescriptions of physicians, the newer public instinctively turn to the druggist for advice in regard to who is the better physician to employ. Upon this most important circumstance there hinge the temptation and injustice of collusion between druggist and doctor for percentage on prescriptions, by which the local field of practice is prejudiced in favor of a certain doctor, with an interested discrimination against his fellow-physicians equally worthy and skilful.

Cajoling themselves into passiveness by the friendly allurements of pharmaceutical convenience and aid, lulled to repose by fancied security, medical practitioners have drifted farther and farther from the fundamental wisdom of guarding and garnering their professional knowledge and advantages instead of confidingly spreading them daily under the caprice and manipulations of persons of acute business instincts, who assume that they cannot, and it is universally known that they *do not*, refrain from subjecting the purpose and province of physician to continuous and damaging trespass. There is awaking in the minds of many medical men a spirit of profound dissatisfaction under the proddings of pharmaceutical infringements, and a growing impulse towards reaction pervades medical thought.

Meetings for consultation have been held by representative members of the Philadelphia Medico-Legal Society and a number of representative druggists, including a professor in the College of Pharmacy, for the purpose of mutually devising some plan for correcting and advancing the interests of our medical and pharmaceutical relations. While the correctness of our attitude was in the main assented to, there was manifested a marked indisposition on the part of several prominent pharmacists to take positive hold of the work of reform, while the burden of the task was placed upon the shoulders of the physicians. It was affirmed by druggists that they could not live by prescription business. But we answer that prescription business is compelled to undergo constant shrinkage through the substitution of patent-nostrum business and various other forms of prescribing by druggists themselves, to which must be here added their high charges for medicines that drive so many people to homœopathy. How can pharmacists expect physicians to sustain a vigorous prescription business if they are cut off by pharmacists in every available way from opportunities of prescribing? Druggists should perceive that in proportion as they foster the rooting and growth of patent-nostrum practice, in proportion as they substitute the physician by making up renewals of prescriptions, in proportion as they intercept the medical functions of the physician by venturing to prescribe for and treat cases of disease, in that threefold proportion do they overstep the pharmaceutical province by invading the physician's legitimate field of professional work, with the inevitable result of curtailing prescriptions and paralyzing legitimate pharmaceutical business.

In the course of these conferences an appeal for the adoption of a mutual medical and pharmaceutical code of ethics was presented, signed by about forty physicians, including the names of several medical college professors and lecturers. While this appeal was not accepted in form by the pharmacists who met with us, it resulted in the presentation of a resolution reviving a section of an old pharmaceutical code that, in practice, had been lost sight of for a score of years. At the conclusion of our appeal for a code we pledged "ourselves to throw the entire weight of our professional patronage in favor of such pharmacists as do in good faith join us in correcting the existing evils of medical and pharmaceutical relations."

The results of the work thus far accomplished are embraced relatively in the three following resolutions, through the practical operation of which it is to be hoped the entire medical profession will at once begin the re-education of the public in their perceptions and estimate of the province of the regular physician.

In regard to patent-medicine abuses,—

"*Resolved*, That the subjects under consideration be referred to the Philadelphia Medico-Legal Society, and that they be requested to send a committee to all respectable druggists, requesting them to place out of sight all patent medicines and

discourage their sales, and all druggists thus agreeing, to subscribe their names to such agreement.

"*Resolved*, That physicians, when writing a prescription which they do not wish renewed, should *write* on the bottom of such prescription, 'Do not renew,' and also inform the patient of the fact in every case; and, on the other hand, the druggist should either *write* or *print* on the label upon the bottle or package, 'Not to be renewed unless by a written order of the doctor.'

"*Resolved*, That as the diagnosis and treatment of disease belong to the province of a distinct profession, and as a pharmaceutical education does not qualify the pharmacist for these responsible offices, he should, where it is practicable, refer applicants for medical aid to a regular physician."

1828 Columbia Avenue.

REMARKS ON SOME POINTS IN THE TREATMENT OF TYPHOID FEVER.

BY WILLIAM PEPPER, A.M., M.D.,

Professor of Clinical Medicine in the University of Pennsylvania.

I HAVE no intention, in the limited time at my disposal, of entering into a full discussion of the treatment of typhoid fever in its various forms and with all its complications, but simply to state in a brief manner the results of my observation as to the management of the ordinary form of this fever, as I have met with it both in hospital and in private practice in this city and its neighborhood.

Although the attempts to isolate the particular poison of typhoid fever have not met with full success, it seems to be generally accepted that this disease is caused by a special *materies morbi*, for the most part admitted to the system through the alimentary canal, although capable, also, of gaining admittance by inhalation. I am disposed myself to believe that this poison is capable of being produced or brought into activity under conditions much more varied than it has recently been the habit to assert.

However this may be, the poison presents certain peculiarities which are important to note from their bearing upon the treatment of the disease. It is undoubtedly capable of retaining its power of infection for a long time latent, so that as soon as proper conditions are present it will manifest activity.

Carefully-observed cases also establish the fact that it is capable of producing typhoid fever although admitted to the system in very minute quantities and much diluted. It seems that the opportunities for the admission of the virus, in such small amounts as have been known to produce typical typhoid fever, must be so frequent and general that a vast majority of the community must at some time or other have been exposed to it. Probably, therefore, it requires, in a degree even greater than do other zymotic poisons, suitable pabulum for its development, and a state of system predisposing to its zymotic action.

At times the virus is so concentrated and active that, in whatever way it gains entrance to the body, it infects the system in nearly every instance and causes a virulent zymosis. On the other hand, the virus may be much less active: so that, supposing it to be taken into the alimentary canal, if the secretions are normal and the glands of the mucous membrane not susceptible or vulnerable, it may be thrown off without the production of the disease. Again, the virus may be more active or more fully propagated in the intestinal canal, and cause marked irritation of the enlarged solitary and Peyerian glands of the mucous membrane, so that the intestinal lesions become considerable; and yet the virus may be arrested in the swollen mesenteric glands and no marked infection of the system occur. This agrees with the well-known fact that no constant relation exists between the degree of intestinal lesion and the intensity of the primary constitutional infection or zymosis.

It is further to be noted that even in cases where primary infection of the system has not been intense, and where the intestinal lesions have been quite marked, it is quite possible, and indeed probably quite frequent, for the morbid intestinal contents to favor further development of the specific virus, and thus endanger continued absorption, or else for the putrid débris and secretions to give rise to a secondary non-specific septicæmia.

It thus seems to me that we must recognize practically the following different primary forms: first, ordinary typhoid fever, with moderate intestinal lesions and mod-

erate zymosis; second, cases with grave intestinal lesions and moderate zymosis; third, cases with grave zymosis and profound constitutional symptoms from the start.

I have spoken of the first form as ordinary typhoid fever, because my own experience would indicate that this and—to a less degree—the second form are by far the most common in this district, although far too frequently individual cases or limited outbreaks of the grave primary zymotic type occur.

I have referred to these familiar views simply to call attention to the immense importance of the rôle which the gastro-intestinal mucous membrane plays in typhoid fever from the earliest moment. It is very important, also, to recognize the fact that the stadium of typhoid fever presents two stages theoretically distinct,—namely, the primary true zymotic stage and the subsequent irritative or secondary septic stage. The first of these is probably the more definite in its duration, lasting, perhaps, from twelve to sixteen days, although the data do not exist for determining its duration accurately.

In speaking of the actual treatment, I would first consider ordinary cases of typhoid fever in private practice, coming under observation at the first development of symptoms of malaise. It is my profound conviction that in a great majority of cases of this form—that is, of course, excluding those of grave primary zymosis—proper treatment of this forming-stage will modify and moderate the whole subsequent course of the case, and will prevent the development of those grave and alarming conditions to the treatment of which so much time and attention are bestowed in most discussions upon this disease.

It is universally recognized that continued exposure and efforts during the forming-stage of typhoid fever greatly increase the gravity and danger of the subsequent attack, and I have often seen patients who, after the symptoms have actually developed themselves, have been allowed to leave the bed merely to use the close-stool or to sit in an easy-chair while the bedclothes were being changed, exhibit early and alarming exhaustion that was at least partially due to these injudicious efforts. The first essential to secure this result should be absolute rest in bed.

I have been surprised to find that some writers who begin by recommending early and complete rest make later allusions which show that their idea of such rest is far from being as thorough as I believe should be enforced. Every case in which the symptoms justify even a suspicion of typhoid fever should, in my opinion, be immediately consigned to bed and the use of the urinal and bed-pan be at once insisted upon. I have even seen such patients, when allowed to leave bed merely to use a close-stool or while the bedclothes were being changed, exhibit such exhaustion at a subsequent stage of the disease as could only be explained by these injudicious efforts. More frequently still have I seen the gastro-intestinal irritation increased seriously by the improper exposure to currents of air while out of bed.

In the next place, a most rigidly restricted diet should be insisted upon. Later in the case more abundant and concentrated nourishment and stimulants will perhaps be called for; but in this forming-stage I believe that a very limited amount of very light nourishment is sufficient, and that its use will exert a happy influence upon the subsequent course of the case. Not only should all solid food be at once forbidden, but the liquid food allowed should be light and very digestible.

Equally important is the avoidance of all irritating medicines, and especially purgatives, at this stage. It is scarcely possible that an emetic or a purgative should remove every particle of the virus from the intestinal canal, and yet we know that the virus will act even when present only in minute quantity and very dilute state if favorable conditions exist; and it is probable that the morbid secretion favored by the action of a purgative in this state of the system constitutes the best possible pabulum for the propagation of the virus, while at the same time it must render the glandular apparatus of the mucous membrane more sensitive and vulnerable. Digestion is disturbed and strength impaired, the intestinal lesions are aggravated, and the case is rendered more serious. If the state of the tongue and secretions indicates a laxative, good results will usually be obtained from the administration of the following:

℞ Hydrargyri chloridi mitis, gr. ii;
Sodii bicarbonatis, gr. xlviii;
M., ft. mas. et div. in pil. no. xii.

Of these one may be taken every two or

three hours until the bowels are moved or until all have been taken, when a movement can be secured by an enema of tepid water or gruel.

During this early stage the remedy which seems to me most constantly called for is quinia, which I am in the habit of giving in larger doses than at the later periods of the disease, except in a particular condition. My reasons for so doing are the following: during this stage the irregular febrile movement frequently simulates a mild malarial attack, and undoubtedly a malarial element is not unfrequently present when true typhoid also exists. Again, it is probable that the use of quinine may lessen the activity of the virus and the danger and degree of infection.

If, however, the gastro-intestinal irritation is at all marked, I invariably administer the quinia by suppository, as follows:

℞ Quiniæ sulph., ʒi;
Pulv. opii, gr. iv;
Ol. theobromæ, q. s.
M. et div. in suppositoria no. xii.
S. One every four, six, or eight hours, while the powders above mentioned are administered by the mouth.

I have found very many attacks of mild gastro-intestinal catarrh, with or without malarial complication, with symptoms closely simulating the early ones of typhoid fever, subside rapidly under the above treatment, together with a diet of chicken- or mutton-broth, gruel, skim-milk, or milk and water in equal proportions.

If, however, the symptoms persist, it can soon be seen that a true typhoid fever is developing, and, if so, the observance of the course above described will have tended much to lessen its gravity. Of course the same absolute, scrupulous observance of rest continues essential. The diet should now be as nourishing as the state of the digestion will permit. I believe, however, that it should be liquid in character throughout the entire course of the disease.

I have repeatedly seen ill results from the infringement of this rule, while I have rarely seen a case where the digestion had been carefully managed from the start in which liquid nourishment did not suffice to maintain nutrition. Indeed, such is my conviction of the supreme importance of the condition of the mucous membranes in this disease, and of the necessity of giving only such food as can be fully digested and absorbed, that I am inclined to believe that far more patients are over-fed than under-fed in typhoid fever.

I have seen many cases where, while beef-tea and pure milk were freely administered, dryness of the tongue, nausea or vomiting, and diarrhœa existed, and where the substitution of light chicken- or mutton-broth, and of skim-milk, or milk diluted with equal parts of water, has led to the subsidence of these symptoms and the re-establishment of good digestion.

With regard to the use of stimulants, I have been led to feel that they are not to be regarded as a necessary part of the routine treatment of typhoid fever. During the early stage of the disease, indeed,—unless exceptional symptoms arise demanding them,—their use is often injurious and tends to increase the derangement of digestion and the gastro-intestinal catarrh then existing. When the early stage is carefully managed, stimulants are often not called for throughout the whole course of the case, or only towards the close to hasten convalescence. On the other hand, in cases where the constitutional infection is serious, and marked nervous prostration and heart-failure exist, their free use may be demanded. No question in the treatment of typhoid fever has seemed to me to rival in difficulty that of deciding, in cases which do not come under notice until high hyperpyrexia, serious nervous symptoms, a rapid and feeble circulation, together with marked derangement of digestion, have supervened, how far these symptoms are the result of nervous exhaustion from protracted surface irritation which may be increased by the free use of stimulants, and how far they are the result of poisoning of the nerve-centres and depression of the vital forces by the zymotic poison.

In such cases it is probably better to use stimulants at once, but with the greatest caution and with a mind fully awake to the fact that their use may aggravate the very symptoms they are given to relieve. Where the case has been under observation from the very beginning, and stimulants have been withheld until the appearance of symptoms actually demanding them, it is generally a comparatively easy matter to determine when they are called for, and to decide in what form and to what extent they shall be given.

In every case of typhoid fever the febrile movement should be carefully watched, and the temperature be recorded two or three times in twenty-four hours,—say at 9 A.M., 2 P.M., 9 P.M. In many cases no special treatment is called for to reduce the temperature. If the primary zymosis is not violent, and the gastro-intestinal irritation is moderated by proper means, the febrile movement preserves its well-known course without the maxima attaining, in most cases, a dangerous point. So long as the temperature fluctuates 2° or thereabouts within each twenty-four hours, and the maximum alone, lasting for a few hours or less, reaches 102° to 103½°, while the nervous symptoms and the heart's action are reasonably favorable, no special anxiety need be felt about the pyrexia. This is especially true in women with sensitive nervous systems and in children, since in them high temperatures are most readily produced and have less serious significance. It is, however, desirable for the comfort of the patient and for the promotion of healthy action of the skin that the surface should be sponged several times daily. The water may contain a little alcohol, vinegar, or carbolic acid, and its temperature should be determined by that of the body and by the sensations of the patient. For instance, in a highly-nervous and delicately-organized young woman of 25 years, with marked typhoid fever in which the maximum daily temperature reached 104°, 104½°, even 105°, for ten or twelve days successively, sponging even with tepid water produced a sense of chilliness, so that it was entirely abandoned, and a perfectly satisfactory recovery was made. I am entirely convinced that any "cold-water treatment" of typhoid fever, with rigid rules for cool bathing, etc., as soon and as often as the temperature reaches a certain point (102½° to 103½° or so on), is unphilosophical, unnecessary, and less successful than the simpler mode of treatment here advocated. The excellent results obtained by some of the advocates of frequent cool bathing show that such baths are well borne and may be safely conjoined with a scrupulous attention to all the other details of rational treatment. But I have preserved the notes of the last one hundred cases of typhoid fever of whose treatment I have had the direction from the beginning of the attack, and the mortality has been but three per cent., and in only five or six of these cases were full baths employed. In the great majority of cases, then, I believe that cool bathing can be dispensed with, and sponging of the surface be found sufficient. But, on the other hand, there are certain conditions that seem to call imperatively for rapid reduction of temperature by cold baths. The first of these is when, early in the case, the temperature rises very high (104½° or over) without any sufficiently severe local irritation to explain it, so that there is clearly a grave zymosis present. Again, when at any period of the disease the daily maximum reaches 105½°, and the daily average is very high, and the hyperpyrexia is maintained despite the free use of cool sponging and the judicious use of antipyretics, cool bathing should, as a rule, be instituted. I follow this rule whether the hyperpyrexia is due apparently to increased septicæmia or to the failure of the inhibitory action of the nervous system; but if severe pulmonary inflammation or a serious exacerbation of intestinal inflammation has occurred to cause it, I do not advise the use of cool baths until the character of the nervous symptoms or the failure of the force of cardiac action indicates that the exalted temperature is producing dangerous secondary results. A few words must be added in regard to the use of other means for reducing hyperpyrexia. Undoubtedly, quinine is the most reliable of these. I have already spoken of its use in the later stages of the disease, either by mouth or rectum, and I think its judicious use thus greatly lessens danger of hyperpyrexia later. When, however, the temperature runs up as the disease advances, it does not seem to me advisable to give large single doses of quinia, but to persevere with the use of twelve to twenty-four grains given in divided doses during the twenty-four hours. The elevation of temperature is so frequently connected with the evolution of gastro-intestinal lesions that it appears desirable to avoid any measure liable to increase this surface irritation. The administration of colossal doses of quinia (twenty-five to forty grains at a single dose), while capable in some cases of lowering the excessive temperature, it seems to me has in more than one instance shown itself to be open to serious objection. If, however, the temperature persistently rises despite absolute rest, judicious

diet, the regular use of quinine in moderate doses, repeated sponging, and if any special reason exists why cool bathing should not be used, or if after cool baths have been used the dangerous hyperpyrexia persists, then only would I recommend the administration of very large doses of quinia; nor would I use them even then unless the state of the stomach encouraged the hope that severe gastric irritation would not result. Digitalis, which is very valuable where failure of the innervation of the heart exists, has not, in my experience, proved itself reliable as an antipyretic or a tonic to the heart when its feeble action results from degeneration of the muscular walls from hyperpyrexia. Salicylic acid and its salts have also disappointed me, often failing to reduce the temperature satisfactorily, and often causing a most unsatisfactory amount of gastro-intestinal irritation.

To return from this consideration of the treatment of the pyrexia in typhoid fever, there is one other condition, and only one, that seems to me to demand attention in every case of this disease. Pulmonary or venous complications may or may not exist in any pronounced degree, but unquestionably there is wide-spread irritation of the gastro-intestinal mucous membrane in every case. This may or may not be so intense as to prove the source of the greatest danger in the case, it may not be associated with severe diarrhœa,—nay, there may not be the slightest diarrhœa present,—and yet there is always hyperæmia and follicular enlargement. Differences between individual constitutions, as well as differences in the degree of these local lesions, cause them to exist in different degrees of reflex irritation, and thus to influence very differently the symptoms and course of the case; but the essential fact is that they are present in every case to an unknown extent, and the obvious inference would seem to be that they should receive suitable treatment in every case.

My own feeling is that this treatment should be instituted as soon as reasonable suspicion exists that the case is one of typhoid fever, and that it should, if possible, be steadily maintained until it may be thought that the mucous membrane has returned to its healthy state. It seems to me altogether probable, even despite the presence of a special poison in the intestinal contents, that some control can be exercised over the extent and progress of these local lesions; and I must add that prolonged clinical observation has convinced me of the truth of this view. The substances which would seem most appropriate for this purpose are the salts of silver and of bismuth and creasote or carbolic acid. Of these my own preference is very decidedly for nitrate of silver, the use of which now constitutes an essential and, in my judgment, a most important part of my treatment of typhoid fever. After the preliminary measures before described, I direct nitrate of silver in the dose of one-quarter or one-sixth of a grain for an adult, usually in pill, or for children in solution in mucilage of acacia three or four times daily, to be taken soon after food. If the bowels are constipated, extract of belladonna is combined; if a tendency to looseness exists, a small amount of powdered opium is added. When given in solution, the opium is added in the form of a few drops of deodorized laudanum. Since I was led to the adoption of this remedy by the study of the morbid anatomy of typhoid fever, I have acquired a constantly-increasing confidence in its value as an element of the rational treatment of this disease. By modifying, as I believe it does, the state of the mucous membrane, it modifies the symptoms that are dependent on the irritation reflected from the mucous membrane; and the result has seemed to me to be that in a long series of cases treated with most scrupulous attention to every detail, and in all of which nitrate of silver was administered, there has been a remarkable freedom from grave complications and a most gratifying percentage of recoveries (ninety-seven per cent.).

As may be inferred from the above remarks, there does not seem to me any objection to the judicious use of opium in typhoid fever. Not only have I seen it useful in checking diarrhœa, but it has often proved the most valuable remedy for the insomnia, headache, and excessive nervous excitability that may be present in this disease. It is true that I have known one of the bromides or chloral or spirit of chloroform produce good results in some cases where such symptoms existed, but far more frequently I have succeeded in relieving them by the use of carefully graduated small doses of deodorized laudanum, given alone, or with sweet spirit of nitre, or with a moderate dose of bromide

of potassium. Not until opium has failed, unless decided constipation exists, do I resort to the use of chloral or the bromides alone.

Time will not allow me to allude in detail to the measures which have proved, in my experience, most valuable in the treatment of the numerous complications of typhoid fever. When bronchitis becomes severe or pneumonia ensues, I substitute carbonate of ammonia for the nitrate of silver, continuing the use of full doses of quinia, increasing the amount of alcohol, and avoiding the use even of sponging with cool water unless the temperature goes over 105° Fahr.

By the observance of a very carefully regulated diet and the early use of nitrate of silver with minute doses of opium, the occurrence of troublesome diarrhœa is rendered rare. When it does occur, the diet should be even more carefully guarded and the amount of opium be increased, and, if necessary, acetate of lead, or a carefully prepared mixture of chalk and bismuth, with an opiate, be administered. Tympanitic distention of the abdomen often resuits from the fermentation of excessive or unsuitable food, and will be relieved by modification of the diet, and the administration of some such combination as the following:

℞ Creasoti purificat., gtt. v vel x;
Bismuthi subnitratis, ʒi vel ʒiss;
Tinct. cardamomi comp., fʒiij;
Aquæ, q. s. ad fʒv.

M. One tablespoonful every six hours.

But often also it comes from a quasi-paralytic condition of the intestinal coats which renders them incapable of resisting the expansive force of the gas enclosed. It is when tympanitis is due to this latter cause, and associated with the general symptoms of prostration and with wasted development of the typhoid state, but without much diarrhœa, that the internal use of oil of turpentine in emulsion (ten drops every three or four hours) will usually produce excellent results.

Belladonna in Salivary Fistula.—Mr. James Allen (*British Medical Journal*) says that in two cases of salivary fistula from injury to the Stenonian duct—one after incision, the other due to a stab—the application of belladonna extract with glycerin over the parotid gland of the affected side was followed by arrest of glandular secretion. The fistula then speedily healed without interference.

TREATMENT OF VESICAL CATARRH BY ESTABLISHING URINARY FISTULÆ.

BY D. HAYES AGNEW, M.D.

IN hopeless cases of chronic cystitis it has occurred to me that the life of the patient might be made comfortable by separating the connection of the ureters with the bladder and bringing them out through the abdominal walls, establishing fistulæ either in the iliac or in the lumbar region, and thereby diverting the urine entirely from the bladder. That such a route for the escape of the urine is not so objectionable as might be supposed will appear from the experience of two persons in this city who suffer from urinary fistula occasioned by accident, one of whom is able to attend to his occupation—that of a daily laborer—by swathing the body with a thick roll of bandage, by which the urine is absorbed. If the fistulæ were favorably situated, mechanical appliances might be constructed in which to receive the urine.

The feasibility of the procedure proposed I have satisfactorily verified by dissection and operation on the cadaver. At first I supposed the proper route to the ureters would be through the loin, as in lumbar colotomy; but the colon on each side is an obstacle which cannot readily be overcome. The plan which I pursued was to make an incision beginning one inch below the anterior extremity of the last rib, and terminating two inches below the anterior superior spinous process of the ilium. After dividing the skin, superficial fascia, external and internal oblique and transversalis muscles, the tranversalis fascia is next broken up, together with the loose tissue connecting the peritoneum with the iliac fossa. It only remains to detach carefully the serous sac until the primitive iliac vessel is reached, at the bifurcation of which into external iliac and internal iliac the ureter will be found to pass into the pelvis. Following the tube down, it should be severed as near to the bladder as possible, two ligatures having been previously applied (the lower one catgut), and the division made between the two threads. To relieve any tension on the ureter, a puncture is next made through the parietes a short distance above the upper angle of the wound, and the urinary duct piloted through by means of a probe secured to

the end of the ligature previously attached to the ureter. It only remains to detach the thread from the duct and to secure the latter by two stitches to the external opening, after which the main wound can be closed. It would not be proper to operate on both ureters at the same time. The patient should be allowed to recover from the first before proceeding to the second. Nor would such a surgical procedure be advisable if there was reason to believe that the kidneys were seriously implicated.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

CLINICAL SERVICE OF THOMAS G. MORTON, M.D.

Reported by C. H. Willits, M.D.

CASE OF TRAUMATIC TETANUS FOLLOWING SEVERE INJURY OF THE SCALP WITH REMOVAL OF A SEQUESTRUM.

GENTLEMEN,—The boy I bring before you, who has just recovered from an attack of tetanus due to a severe injury of the scalp, presents about this history:

He is 13 years of age; was admitted on the 22d of September, suffering from an extensive laceration of the occipital region, fracture of the left clavicle, fracture of about four ribs, and many contusions and abrasions. He was knocked down by a train of cars in slow motion, was carried under clear of the wheels, but was caught, pinched, and rolled between the axle of the car and the ground. The scalp covering the entire occipital portion of the skull was torn down and hung upon the neck; the skull underneath it was denuded of the pericranium, and the surface of the bone much roughened.

The boy was evidently caught by the shoulders and squeezed together, as the left clavicle was fractured at its middle, the second, third, fourth, and fifth ribs of the left side had started from their sternal articulations, and one or two of the ribs of the right side were fractured. His right shoulder was much bruised, he was covered with contusions and abrasions, and he was in a state of profound shock.

His arm was placed across his chest to reduce the deformity of the clavicle, carbolized dressings were applied to the scalp-wound, and external warmth, stimulants, and hot beef-tea were ordered until reaction took place. The boy slowly recovered from the shock, and the scalp-flap, which was dressed with carbolized oil, without any tension, did not slough, but discharged pus freely.

His condition remained good until the 8th of October, when he evinced symptoms of tetanus, shown in attacks of trismus, opisthotonus, and general rigidity at intervals for several days. He was immediately placed upon the use of morphia by hypodermic injections in quarter-grain doses, with one fourth of a drop of conia, soon increased to one-half, every two hours; liquid diet, and stimulants. Under this treatment his symptoms gradually grew better, and he was able to leave his bed on the 12th of this month.

It has now been two months since the injury, and you can see a large ulcer and slough covering the occiput, with a piece of dead bone protruding in the wound. This sequestrum, I think, is a portion of the external table, and when I remove it, which I will endeavor now to do, it will leave beneath it healthy granulations. I grasp it firmly with the forceps, and gradually pull it out, displaying beneath a mass of healthy florid granulations which nature has thrown out between the living and dead bone. This ulcer will be dressed with a soft oil dressing, and our patient will soon be entirely cured.

TENOTOMY FOR A CASE OF SCROFULOUS DISEASE OF THE JOINTS.

This patient, a deformed boy, is suffering from the contractures incident to a scrofulous affection of the joints. Some time ago I performed the operation of tenotomy upon the hamstrings of the right ham and straightened the limb, and then applied a posterior splint; and I propose this morning to repeat the operation upon the left leg.

When he was admitted, some time ago, he was suffering from the injudicious use of opium, which he used himself in the form of morphia hypodermically. You will see, by the scarred condition of his body, that almost every available spot except the face shows evidences of the needle. Following its introduction abscesses often took place, due partly to the impoverished condition of his blood. At the time, his urine was albuminous, being nearly one-quarter the bulk albumen; but it cleared completely under the use of Basham's mixture and the stoppage of the morphia.

In September last I had decided to operate upon the left leg, when his urine again showed evidences of albumen, which proved the precursor of an attack of erysipelas. He recovered, and now his urine is perfectly clear, and he is in such good condition that I have no hesitation in endeavoring to restore the position of the limb.

In club-foot operations, in which tenotomy is so frequently employed, an accident could hardly happen, unless it should be the division of the posterior tibial artery, which could be readily controlled by pressure. Of course, when you come higher up, as the ham-string tendons, great care should be exercised that no important structures in the popliteal space are injured in the passage of the knife.

I find, as I grasp the joint, that there have been some inflammatory changes, a process of thickening which does not amount to anchylosis, and which I can nearly overcome by forcibly extending the limb. As I do so, thus making the ham-strings tense, I pass my knife under the tendons of the semi-membranosus and semi-tendinosus, and, pressing the blade against them, feel them give way. This gives the limb a sufficiently good position without the division of the biceps tendon. I now dress the limb in a posterior, straight, pasteboard splint, firmly bandaged.

In overcoming anchyloses in these deformed joints, separation of the epiphysis may take place and even the bones may yield, but the fractures always heal kindly and with excellent results.

It has now become a common procedure in my practice, in treating different angular deformities with anchylosis at the hip, after anæsthesia, to leave the pelvis well secured, then to forcibly fracture the neck of the femur, and then to apply extension in a straight position and treat it as an ordinary fracture. This has, in a large number of cases, replaced excision, simple section, and other modes of treatment, and I have never had any unfavorable symptoms arise, but good has been the invariable result.

Rickets.—The three last meetings of the London Pathological Society have been occupied by a debate on rickets. The *Lancet* warns intending readers of the debate that they will find but little of the nature of recorded fact or observation, while there is an abundance of theory.

TRANSLATIONS.

Muscular Atrophy of Articular Origin.—Dr. Debove (*Le Progrès Méd.*, 1880, p. 1011) says that the considerable deformities brought about by articular rheumatism in part involve the bones, and in part produce contraction or atrophy of the muscles. He has recently had an opportunity to study this atrophy *post mortem*, with the following results. In the old classical descriptions of this trouble writers contented themselves by asserting that under the influence of immobility of the part atrophy with fatty degeneration of the muscles was brought about. Examination now shows that a quite different condition exists. The subject had suffered a long time with articular rheumatism; most of the joints were the seat of rheumatismal changes, and the muscles were considerably diminished in volume; they were found of a yellowish, dead-leaf color. Their muscular fibres, examined under the microscope, showed signs of simple atrophic change without fatty degeneration. In similar cases various coexistent appearances of the muscles might, indeed, lead to the idea that fatty degeneration had occurred, as, for instance, the yellow color, due probably, however, to diminution of the muscular hæmoglobin. The direction of the sections also might lead to mistakes, inasmuch as there is in some cases interstitial lipomatosis, fatty vesicles interposing themselves between the fibres if the sections are made parallel to the direction of the latter, so that it is difficult to say whether the fatty matter is external to or within the sarcolemma. To avoid this difficulty sections should be made perpendicular to the axis of the fibres. In the case in question, the alterations in the muscle presented two characteristics which brought it into relation with myopathy of nervous origin,—namely, the irregularity of the atrophy and the sclerosis of the interstitial connective tissue. The atrophy in the case examined was not equal: not only did it affect certain muscles in preference to others, but in a given fasciculus certain fibres could be observed which were reduced to one-third or one-fourth of their volume, some even only appearing as a red point tinged with carmine. The atrophy, therefore, was not uniform, but affected

only certain fasciculi of the muscle. The connective tissue between the diseased fibres was more abundant and more dense. This irregularity in atrophy has been observed in progressive muscular atrophy, and also by Debove in the muscular atrophy of hemiplegics and paraplegics. On the other hand, the atrophy observed in cachectic cases when the emaciation has been extreme is even throughout, and the interfibrillar connective tissue is not more abundant than in the normal condition. The resemblance presented in atrophy of muscular origin to that of nervous origin has long since suggested the idea of a central or peripheral nerve-lesion on which the articular and muscular lesion might depend. Dr. Debove's examinations, however, have thus far failed to show any lesion of the medulla. The cells of the anterior horns of the medullary gray substance possessed in the case examined their normal appearance. The larger nerve-trunks, however, and even the smaller branches examined to their distribution in the muscles, presented the extremest degree of atrophy.

Operative Procedure in Strangulated Umbilical Hernia.—Dr. Terrier at a recent meeting of the Société de Chirurgie (*La France Méd.*, 1881, p. 34) said that the therapeutics of this affection have been the subject of numerous discussions. Huguier thought that no operation should be attempted. Gosselin, on the other hand, thought that the prognosis of the affection had been made unnecessarily grave, and that if the operation is performed quickly and under favorable conditions success may be hoped for. M. Duplay, while recommending the operation, thought that the smallest possible wound should be made in the peritoneum. Dr. Terrier himself had observed three cases of strangulated umbilical hernia which had been operated on, and he would give the notes. The first was a woman of 77 who had long suffered from an enormous umbilical hernia. She was brought to the hospital with symptoms of strangulation. Dr. Terrier made a long vertical incision, and easily opened the hernial sac without finding a trace of peritonitis. The patient died, however, in the course of a few hours. At the autopsy an intestinal loop was found issuing from the abdominal cavity, which passed through the subcutaneous cellular tissue and returned to the abdomen.

A second case was that of a man in whom the hernia had been strangulated thirty-six hours. It was a small umbilical hernia; the sac was thin and covered with adipose tissue; it contained a small loop of the congested small intestine. Three nicks were made and a cure effected without difficulty, the neck of the sac joining by first intention.

The third case was that of a woman of 45 who had suffered with an umbilical hernia since 1861. Twice symptoms of strangulation had occurred, but reduction had been made without difficulty. The third time reduction was impossible. Operation showed a mass of epiploön in the middle of which was a loop of intestine twelve centimetres in length. After having effected reduction, Dr. Terrier placed a drainage-tube in position. The patient recovered. In conclusion, this success in two cases out of three without any particular operative procedure shows that umbilical hernia, contrary to the opinion generally stated, can be cured by operation.

In the discussion following the reading of this paper Dr. Polaillon mentioned three cases in which he had operated,—twice successfully. Dr. Verneuil thought better not to operate. Dr. Trélat, however, considered that, as the methods of after-treatment were so much improved since the time of Malgaigne, who had advised against operating, operation was now justifiable.

Lipoma of the Tongue.—Guelliot (*Le Progrès Méd.*, 1880, p. 1014) observed in Prof. Gosselin's wards a man of 48 who had had a tumor on his tongue for twenty-five years. This tumor, which had at first appeared as a small tubercle, had grown gradually with the lapse of years until it became large enough to involve the buccopharyngeal opening and interfere greatly with respiration. The tumor, which had a large pedicle, was situated on the anterior and right border of the tongue two centimetres from the median groove, but lying on the superior surface of the organ. It was not deep, being evidently situated on the mucous membrane. Somewhat lobulated, its surface was of a pale rose color with a yellowish tint in some places, while in others the collected epithelium gave it a white color. The mucous membrane covering it was thin and without papillæ; there was slight ulceration at one

point. To the touch it was soft, fluctuating, but not transparent. General and special sensibility of the surface seemed to be wanting. The tumor was evidently benign, and the diagnosis lay between a cyst and lipoma. In favor of the former, the special softness of the tumor and its want of transparency might betoken a cyst with thick walls. In favor of lipoma was its seat on the dorsum of the tongue, its opacity, softness, and the yellowish look of the mucous membrane covering it. It is true that it had not the lobulated feeling usual in adipose tumors. However, this diagnosis was made, and the tumor removed with the scissors after passing a double elastic ligature through the pedicle and around it. Examination showed the adipose character of the growth, the lobules being separated by very thin connective tissue. Lipomata of the tongue are very rare. Guelliot could find but twelve cases on record.

Purulent Infection in the Course of Suppurative Thyroiditis which had not been opened to the Air. — Oulment (*La France Méd.; Cbl. f. Chir.*, 1880, p. 767) reports the case of a woman 26 years of age who had suffered for eighteen years with a thyroidal enlargement. Whenever she menstruated she was attacked by facial erysipelas, which, however, ran a rapid and favorable course. On her admission to the hospital she complained not so much of the erysipelas as of a painful swelling of the cervical tumor, accompanied by fever and extreme prostration. In the eleven days following her admission she suffered from repeated chills, with diarrhœa, dyspnœa, and swellings in the left elbow and ankle-joint, going on until the patient gradually failed and died with symptoms of profound septic poisoning. At the autopsy, purulent collections were found in the thyroid gland, both the joints mentioned, infarctions in the kidneys, and bacteria in the blood. Oulment considers the condition of the uterus in menstruation as the predisposing cause, and cites the case of a midwife who, passing unscathed among cases of puerperal septicæmia, finally attended a case while menstruating and became the subject of purulent infection. In other cases the intestines may be regarded as the portal by which infection may enter, particularly when, as was the case in the present instance, the organism is weakened.

Action of Blisters on Sensibility.— M. Grasset gives the case of a man who was suffering from left-sided hemi-anæsthesia, said to be of six years' duration, and in whom right-sided hemi-anæsthesia had been previously and unexpectedly removed by a blister applied for pleurisy. The application of a blister over the deltoid was followed by the return of sensibility in the greater part of the limb. The restoration of sensibility did not, however, occur first in the neighborhood of the blister, but in the hand, and it extended as far as a little above the elbow, the neighborhood of the blister remaining insensitive. Another blister was then applied to the thigh, and was followed by a recovery of sensibility in the whole leg. The loss of sensation was thus reduced to the left half of the trunk, neck, and face. M. Robin found some time ago that saturnine hemi-anæsthesia could be removed by the action of jaborandi, the diaphoresis appearing to be attended with a return of sensibility. The use of the drug was also suggested to M. Grasset by a remark of his patient that he only sweated on the unaffected side. Jaborandi was used here with good effect.

New Contribution to the Therapeutic Applications of Iodoform.—Dr. Aphel (*Jour. des Sci. Méd.*, 1880, p. 612; from *Lo Spallanzani*) gives the case of a woman of 20 who had received a contusion of the right mamma, which soon became painful, while the lymphatics of the axilla also became engorged. After suffering for twenty days, the patient sought medical relief. Inunctions with a pomade of mercury and belladonna, persevered in for ten days, gave no relief. On using an ointment of iodoform, however, instantaneous relief was gained. At the end of ten days the patient was discharged cured. In a second case, that of a man who received a severe bruise on the ankle, an ointment of one part of iodoform to thirty of lard produced rapid amelioration. Prof. Masius uses the following formula: iodoform 1 part, glycerol of starch 30 parts, essence of peppermint a sufficient quantity to mask the odor.

Treatment of Dyspnœa by Salicylate of Sodium.—Salicylate of sodium is recommended in dysmenorrhœa of purely nervous origin, and also in gouty or rheumatic dysmenorrhœa. It is less efficient in other forms, but is, however, useful in these also.

EDITORIAL.

ALUMNI SOCIETIES.

IN the course of a very few weeks most of the medical colleges of the country will close their sessions with appropriate ceremonies, and among the various procedures meetings of alumni societies will no doubt be prominent. In our youthful days these societies were not; in this city, at least, they are a modern innovation, and, we think, on the whole, a good one. They were originally called into being by the various faculties as a means of extending their own influence, of creating and maintaining a spirit of unswerving loyalty to the respective institutions, and thereby filling the pockets of professors. The exact boundary of the true disinterestedness of the professors in their action is exemplified by the rapidity with which a well-known gentleman—who had been most eager in getting up an alumni society, most unsparing in his condemnation of sister-institutions, most earnest in his protestation of the superiority of his own body—left his post when offered a few more dollars annually by a rival college. The birth of these societies was not altogether noble, but the societies exist. It is time, however, for them—no longer infants in age, feeding upon the pap administered by hopeful and admiring faculties—to look about them and act for themselves. If we mistake not, it is possible that what was a nursling of soft and gentle mien may grow into a Hercules eager to labor for the right.

Viewed purely as a commercial transaction, the contract which is fulfilled when the student receives his diploma from an ordinary medical college leaves no one under obligation. The student has *paid* his fees to the professors, and received his knowledge and his right to practise, and that is the end of it. The faculty are at least under as much obligation to him as he is to them. On the other hand, institutions of learning properly endowed give more to the student than he gives directly back. The object of endowment is to furnish to the student for a hundred dollars that which costs two or more hundred,—in other words, to pay, in whole or in part, the expenses of his education. To such an institution a student owes a debt, and he is morally bound until, by direct gifts, or by interesting others more able to give than he is himself, or by enlarging the classes of his *alma mater*, he has made return for that which has been bestowed upon him.

It is plain that our medical colleges under the old system put no such obligation upon their students. Loyalty is a good quality; but a persistent, unreasoning loyalty may be a very bad thing. There still are large colleges which make no more than a hollow pretence of reform, into whose crowded rooms are gathered and out of whose crowded rooms are annually discharged into their communities large numbers of men with but a show of regard to qualification, whilst the faculties receive princely incomes for a minimum of labor. Is there ground for love by worthy men of these institutions? Perhaps so; but the love should show itself by disciplining the institutions. It is a false pride, an evil loyalty, which leads a physician to send his students to an institution which he feels is being managed not for the general good, but to fill as rapidly as possible the pockets of those who are incumbents in the various chairs and are their own managers, so far as policy and action of the institutions are concerned.

Under these circumstances, ought the alumni societies to disband? are they an evil? By no means. Association

brings power, and what each alumni society should do is to use every effort to extend and strengthen its influence,—not only to knit its membership more closely together, but also to increase its numbers until it includes, as near as may be, all living graduates, and then to employ this power. Any such body of men could force their *alma mater* into the right path of progress. If the Alumni Association of the Jefferson Medical College was so organized, and would assert itself, is it probable that the institution would remain where it now is, holding a position so well known that it is not necessary to specify it?

Again, even in such an institution as the University of Pennsylvania, where the faculty have sacrificed their pecuniary interests to the general weal, the Alumni Society ought to assert itself and leave no stone unturned until it has obtained representation in the Board of Trustees. It owes this to itself, but it owes it also to the general medical profession. When representation is gained, as we believe it readily can be, in the University Board of Trustees, other alumni societies will grow restless with a sense of want and of power; tempests will gather; and when at last medical colleges are ruled, at least in part, by medical men whose eyes are not dazzled by the gilded glitter of self-interest, the millennium will not have come, but we shall have made a step towards it.

LEADING ARTICLES.

FOOD-ADULTERATION.

MUCH attention has of late been called to the subject of food-adulteration in this country, first by the various sensational and contradictory reports of such adulteration which went the rounds of the "scientific" and popular press, and more recently by the offer of a reward for the best draft of an act to prevent the falsification of articles of food in common use, offered by the National Board of Trade.

What has been needed, and what, until quite recently, has been almost entirely wanting, has been trustworthy data upon which to found correct notions of the prevalence and degree to which the various articles of food found in commerce have been adulterated. Is our vinegar indeed sulphuric acid? are our pickles incrusted with verdigris? is our bread a mass of alum? Is coffee a euphemistic expression for a decoction of the leguminosæ of our gardens with a dash of chiccory, and the milk with which it is mingled a mess of chalk, calves' brains, and pump-water from a possibly sewage-infected well?

Fortunately, the subject has now been taken up and reported upon by competent investigators, and, although the examinations made have not been as numerous or as widely extended as could have been wished, yet enough is known to calm the fears of the apprehensive, and to indicate that for the present the American citizen may eat his meals in the peaceful consciousness that for the most part his food is what it professes to be, and that he is not being slowly poisoned by toxic chemicals insidiously mingled with his daily aliment.

Dr. Charles Smart, U.S.A., in a supplement to the *National Board of Health Bulletin*, published at the beginning of the present year, gives the results of an investigation to determine the prevalence of adulteration in food-supplies. This investigation, which was undertaken in accordance with instructions from the National Board of Health, includes the examination of seven hundred and thirteen samples. Some difficulty was experienced in collecting these, owing to want of co-operation on the part of State and municipal health boards, and to the scanty appropriation available for the purpose. Specimens were collected from two sources: first, from first-class stores and from the army commissary department, where adulterated articles were not to be looked for; and second, from sources which might be presumed to yield low-grade, if not adulterated, goods.

Of the seven hundred and thirteen examples examined, three hundred and four were obtained from sources which implied purity, as already explained, and four hundred and nine from those which might be considered suspicious. Of the former, twenty-four, or 7.89 per cent., were found to be of such a character that under a law repressive of fraudulent adulteration prose-

cution might have been instituted with full prospect of effecting conviction. Of the latter, one hundred and eighty-three, or 44.74 per cent., would have been in like manner condemned. Dr. Smart's results respecting the various articles examined are of so much interest that we append an abstract of his report.

Lard and *corn-meal* were found to be unadulterated.

Tea was indeed found to be mingled with Prussian blue and indigo, but the quantity of these drugs employed for the purpose of facing the leaves is so small as not to be deleterious. If the color hid the quality of the leaf, so that a poor tea might be passed off as a superior article, some action might be warranted; but the color can be removed easily and the leaves judged by their natural appearance. Indeed, the facing in itself constitutes a criterion of quality, it being invariably fine or coarse as the leaves are young and high-priced or old and cheap. The facing seldom adds materially to the weight. Of ninety-eight specimens taken from sources where purity was to be expected, all were found pure. Of nineteen specimens taken from sources where adulteration might be expected, five were found adulterated. One of these had an excess of lime sulphate facing, one was mixed with sand, and three were mixed with exhausted leaves.

Coffee, Dr. Smart thinks, is not apt to be extensively adulterated in this country, owing to the fact that the American housewife prefers to buy the whole berry and to grind it in the domestic machine. Mr. Hill's examination for the State Board of Health of Massachusetts showed that ten samples of ground coffee obtained in bulk were found to be pure, while seven package samples consisted of one with no coffee, two with very little, and four with 50 to 70 per cent. of coffee, the rest being roasted wheat, pease, beans, and chiccory. Dr. Smart, however, found that some loose ground coffee examined by him contained chiccory and beans. Only one sample of package "coffee" was examined. It contained chiccory, corn, wheat, and rye, but no coffee. Three extracts or essences of coffee were examined, one of which consisted of chiccory and the two others of roasted starches. Two of these bore on the label an offer of reward for proof that any other extract of coffee was as pure as they!

Sugars and *syrups* were not found to contain sand except as an accidental impurity. Of one hundred and twenty-four samples of all kinds of sugars examined by Dr. Smart, fifty-seven were microscopically clean; sixty-four contained accidental dust; three were foul and swarmed with the sugar-mite. Of late years a saccharine substance, glucose, less sweet than cane-sugar, but, so far as known, possessing all its nutritive qualities, has been manufactured from starch by boiling with sulphuric acid and afterwards removing the acid by means of lime. It has been asserted that this substance is largely used for the fraudulent adulteration of sugars. In spite of reports to the contrary by public analysts of England and the health authorities of New York, adulteration by glucose is certainly practised. Among forty-seven brown sugars furnished Dr. Smart by dealers who knew they were to be examined, three contained glucose; while among thirty-eight samples purchased for analysis, no less than nine were thus adulterated. The glucose varied from a small admixture to thirty per cent. The white sugars, powdered, granulated, etc., were free from this adulteration. The syrups, of which twenty-one were sent in for examination and twelve were purchased, were all found to be pure. No salts of tin or other unwholesome substances sometimes stated to be used by refiners were found in the specimens either of sugar or of syrups.

The results of the *flour* analyses were highly gratifying. Of fifty-eight specimens which were examined, only one contained matter foreign to the wheat-kernel, and in this case the adventitious substance was corn-meal, evidently introduced by accident. Five samples were so deficient in gluten that it was doubtful if good bread could have been made from them; but this arose, not from wilful adulteration, but from natural causes. This result is very different from that found in England, where even last year, in spite of the stringent laws, fifteen specimens in six hundred and seven were found adulterated with alum.

Bread was found by Dr. Smart to contain alum in appreciable quantity. The unwholesomeness of alum is, however, by no means universally accepted. If the alum existed in bread as alum, and was introduced into the system as such, it would, from its powerful astringent quali-

ties, interfere materially with digestion and be properly viewed as a deleterious ingredient. But it is well known to chemists that when water is added to alumed flour in the process of dough-making, a chemical change takes place whereby the alum is converted into an insoluble powder. This insoluble powder, which is generally believed to be inert, has been proved by Professor Patrick, of the University of Kansas, to be unaffected by the juices of the stomach. Alum would, therefore, appear to be harmless. But there is another view to be taken of the subject, looking to its action in the bread itself. One of the objects of its introduction is to check the process of fermentation which may be taking place in poor flour: so that the bread made therefrom is whiter and contains less dextrin and starch-sugar than if no alum had been added. So far its action is preservative and of value, but it is accomplished at the expense of the nutritive principles of the flour. Phosphoric acid, from the soluble phosphates of the grain, is precipitated along with the insoluble alumina in the bread-making process, and, what is of more consequence, the digestibility of the bread is impaired by the presence of the alumina and its phosphate. J. West-Knights, F.C.S., in a paper read before the Society of Public Analysts during the past year, records the results of digestive experiments on alumed and unalumed breads. The former left a larger residue of unsolved matter after treatment with an artificial gastric juice. Nevertheless, there are no cases on record where disorder of the digestion is unmistakably due to the use of alum. There are many declamatory and unsound passages in books concerning the unwholesomeness of alum in bread; but, impartially viewed, the evidence appears to give ground for regarding it as an adulteration which should be suppressed. As alumed baking-powders are in such general use, this subject is worthy of a thorough investigation.

Dr. Elwyn Waller, in the fourth annual report of the Health Department of the city of New York, reports upon the bread sold in that city: Of fifty-one samples, forty-one contained no adulterant, two contained copper, probably added as sulphate, six contained an excess of alumina, and two both alum and copper.

Alum, however, was the only adulteration found during the present investigation.

Bicarbonate of soda, of which only twelve specimens were examined, was found to be considerably adulterated with sulphates and chlorides. No markedly fraudulent adulterations, as with large percentages of terra alba or starch, were discovered; but it is probable that if the list of samples had been increased some notably bad specimens might have been obtained, for in twenty-eight samples reported in the third annual report of the Health Department of the city of New York, while twenty-six were of the ordinary commercial character, one contained flour, and one nearly twenty-five per cent. of terra alba.

Cream of tartar is one of the articles which is subject to gross adulteration. Of eighteen samples examined, six were of satisfactory purity, eleven contained sulphate of lime varying from seventeen to ninety per cent., three having nearly the latter figure, two contained no cream of tartar, but consisted instead, the one of sulphate of lime, alum, and acid phosphate of lime, and the other of alum, acid phosphate, and potato-starch. Considering the use of cream of tartar in baking, its impure condition is a serious evil.

Baking-powders, of which six specimens were purchased and twelve obtained from the United States commissary department, were found to differ according to their origin, the army supplies being in every case pure and the others all impure and some deleterious.

Black pepper, ground.—The examination of the ground black peppers and spices shows to what extent adulteration may be practised when its detection by the public is a matter of difficulty. The dealer himself appears to have lost the knowledge of the characters of the pure article, as, out of four samples sent in by respectable houses in Washington for the purpose of being examined, only one was pure. The others contained baked flour and rice, with sand enough to prove the unclean condition of the peppers when milled.

Of the other spices, *allspice* when ground was found to be largely mixed with bread-crusts, beans, corn-starch, woody tissues, and turmeric. Of twenty-three purchased specimens, eleven were allspice only in name. Of eleven purchased samples of ground *ginger*, six contained wheat-flour, corn-starch, rice, bran of wheat, husks of black pepper, and turmeric. Some of these

contained over five per cent. of sand. Ground *mace* was found to be almost universally adulterated, the real composition of the supposed spice being made up of corn- and wheat-flours and starches, wheat-bran, rice, beans, and turmeric. Even three samples presented for examination by first-class houses were not all pure; one was mixed with wheat-starch. Of ground *cloves*, four examples from unexceptionable sources were found to be pure, but only three of twenty purchased specimens were free of other and cheaper vegetable substances. It would appear that pure ground *cinnamon* is an unknown article of commerce. Of twenty-six samples, only one, and that supplied by the commissary department of the army, was unadulterated. Ground *cayenne pepper* is as rare an article in the market as ground cinnamon. Fortunately, red lead, which Hassall found so frequently in English samples, appears to be absent in the American article,—a good instance of the ameliorating effect of republican principles on commercial morality. *Mustard* fares no better than other spices: twenty-one adulterated specimens were found out of twenty-seven, comprising *all* those purchased in the open market. *Vinegar* was found to be adulterated only by the addition of water. No copper, lead, or other dangerous metals were found, nor any free mineral acid. Of *pickles*, only one sample was examined, which proved to be pure. Recently, Professor Bailey found copper equivalent to one-seventh of a grain of sulphate of copper in a bright-green pickled cucumber weighing two ounces. But little *confectionery* was examined, and only the yellow-colored candies were found to contain poisonous coloring-matter, the color here being due to chromate of lead.

In conclusion, we may congratulate our readers and the public that matters are no worse. Our advice to Paterfamilias is briefly as follows. Buy your flour, tea, and sugar from reputable tradesmen, and never purchase ground coffee and spices. Above all, do not, for the purpose of gaining a temporary period of peace and quiet, give your children *yellow* sour-balls to stop their little mouths. For if you do you may be obliged, later, to spend sleepless nights in the attempt to assuage the pangs of a colica pictonum, which the wiser purchase of *red* "sour-balls" colored with the harmless cochineal might have prevented.

CORRESPONDENCE.

LONDON LETTER.

THE subject which has largely engrossed my attention the last day or two is the instructiveness of the urine in cardiac dropsy in the light it throws on several aspects of the subject. Not only does it possess a high interest of its own, but it illustrates changes in the circulation in some other maladies in an instructive manner. Further, it can be shown to have a high prognostic value in wider senses than is usually appreciated, and also to carry with it useful lessons in therapeutics. We all are familiar with the aspect of the urine in advanced cardiac disease: it is scanty, light-colored, dense, and readily throws down a deposit, usually of a reddish color. As the dropsy increases, this appearance is intensified, and usually in time some albumen shows itself. Now, it may be well to consider these points *seriatim* and in order.

The bulk of urine is intimately related with the blood-pressure in the arteries. When the blood-pressure is high, the bulk of urine is large; when the blood-pressure falls, the bulk of urine is less. That is, speaking broadly and not going into minutiæ,—such as questions of obstruction in the pelvis, of the kidneys, or the ureter, and like disturbing factors, which interfere somewhat with the broad generalization,—but accepting the statement that, ordinarily, the bulk of urine is the measure of the blood-pressure in the arteries. Consequently, when the walls of the heart commence to yield, with or without mitral disease, and the left ventricle can no longer keep the arteries well filled with blood, the bulk of urine falls below the normal. Step by step, hand in hand, together, the bulk of urine falls as the cardiac contractions decline in vigor. We know that the blood-pressure in the glomeruli of the kidney determines the rate at which the water of the blood, and the matters held in solution therein, pass from the blood-vessels into the urine-tubules of the kidneys. When a draught of water is taken and the water rapidly passes from the stomach into the circulation, the blood-vessels are filled; and then rapid secretion of urine follows. If we are perspiring freely, then the water passes off by the skin, and the bulk of urine is little increased. So we may say that when the skin is freely acting the bulk of urine is small; in cold weather, when the skin is inactive, the bulk of urine is large. When the blood-pressure in the arteries is light, as it is in the early stages of the gouty heart and kidneys, then there is a free flow of urine of low specific gravity. We know that when we meet a case presenting the following features,—a tight incompressible pulse, a hypertrophic left ventricle, a loud second sound heard over the aortic valves, and a copious flow of urine of low specific gravity,—we have

before us a case of the gouty heart with cirrhosing kidneys, whether or not there be albumen in the urine. Here we have, in other words, a dilute urine. As long as the contractions of the left ventricle are vigorous, so long is the bulk of urine large; but when muscular failure sets in, then the bulk of urine falls. The bulk of urine is the outward visible sign of the inward morbid changes, and the fall tells that molecular decay is spreading throughout the muscular fibrillæ of the hypertrophied ventricle. It is, then, the herald of coming change, or rather of histological change so well established that the heart's power is being enfeebled. As the cardiac power wanes, so the bulk of urine falls, till in time the copious dilute urine has given way to a scanty concentrated urine, in fact. This tells that the features of the gouty heart in its early stages are being lost in those of cardiac failure. The change is like that of a dissolving view: it is not sudden, it is gradual. The characters of one view are lost, and those of another gradually show through them; at either extreme a clear view is to be had, but at the time when one set are disappearing, and the other beginning to show through them, there is a certain indistinctness, a certain blending of the two, which is puzzling in the extreme. So it is with a case when the features of the strong gouty heart are being merged into and ultimately lost in those of cardiac failure. In time the features are those of heart-failure, not to be distinguished by the casual observer from those of an advanced mitral disease; still, the hard arteries and the distinct aortic second sound tell of what once has been to those who are familiar with these cases. Consequently, as the artery is less and less filled by the failing ventricular systole, so the bulk of urine falls, until there comes at last the dense, scanty, high-colored, concentrated urine of cardiac dropsy. The water, instead of finding its way out by the kidney, has found its way into the areolar tissues of the body, and dropsy is established.

This diminution of the bulk of urine is, then, most significant of cardiac failure,—either temporary or permanent, as the case may be, but ultimately prominent enough in spite of everything we can do. So in fevers where there is vaso-motor dilatation, the bulk of urine is small in spite of the patient taking large quantities of fluids. As the artery slackens, the urine becomes less in bulk,—becomes, indeed, a concentrated urine. When the pyrexia passes away, then the bulk of urine is increased until a normal bulk is regained. So it is with the concentrated urine of cardiac adynamy. If we can restore the vigor of the ventricular contractions, and enable the ventricle to fill once more the arterial system fairly well, then the outward evidence of this is the increased bulk of urine. As the water once more is squeezed out into the urine-tubules, the blood takes up again the water from the areolar tissue, or, in other words, the atophy disappears. But in time the dropsy reappears, and the measures adopted for its removal prove futile; the bulk of urine is but little and only temporarily affected by the remedial measures once so successful; and then we recognize the unpleasant fact that the case is passing into its final stages. We know only too painfully well that the molecular decay, the fatty necrosis of the muscular fibrillæ of the heart-wall, is spreading throughout the substance of the heart so extensively that the vigor of its contractions is gone, never to return. The treatment is made more active; temporary improvement follows, but it is delusive. The improvement does not continue, and the case moves onward to its conclusion. Now, for the treatment of this condition of dropsy we possess two different measures, which, however, are not incompatible with each other,—indeed, which can with advantage be used together. The one is to increase the vigor of the ventricular contractions, and so to increase the outflow of water by the kidneys; and for this purpose it is well to administer digitalis or some other drug of allied character. It is well, too, to administer some strychnine along with the digitalis, especially if the breathing is embarrassed, as is often the case. The strychnine acts upon the respiratory centre and improves the respiratory efforts. The impression upon the respiration is a useful auxiliary to the action of the digitalis upon the heart, and the circulation (between the two) is greatly improved. The arteries are better filled and the bulk of urine is increased. The other measure is to drain the water out of the system by hydragogue cathartics or the hot-air baths, exciting free diaphoresis, or both. It is well to bring the heart under the influence of the digitalis for a day or two before starting either of the other measures, in order to do away practically with any risk of serious syncope under their action. These secretory measures may be continued for a week or two,—each twice a week; then each once a week for a week or two longer, if any dropsy remains. Such, then, are the measures for relieving the dropsy and improving the circulation. The relief of the venous congestion by these measures of catharsis and diaphoresis removes the venous fulness in the kidneys and allows of a freer flow of blood through them, thus aiding the action of the digitalis directly upon the arterial fulness.

The bulk of urine is the outward indication of the state of arterial fulness: the fuller the artery, the greater the bulk of urine. Now let us consider the presence of albumen in the urine. No amount of pressure within the arteries will bring about an albuminous condition in the urine,—even ligature of the aorta below the renal vessels fails to produce it,—but any obstruction to the venous outflow

from the kidneys sets it up. Consequently, the amount of albumen in the urine is the measure of the venous fulness. In some cases it shows itself early, in others only at the near approach to the termination of the case. Usually it appears when the venous engorgement is becoming considerable,—at first fitfully, then more persistingly, finally permanently. Whenever the measures adopted improve the circulation, and with it the bulk of urine, the albumen disappears, wholly or partially. When the bulk of urine again falls, the albumen reappears. As the case progresses to its final stages, the presence of albumen becomes established, and its amount steadily increases and the case grows worse. In so speaking of albuminuria here, I mean the albuminuria of venous congestion, without any reference to any albuminuria which may have been pre-existing and which is not the distinct product of venous fulness. Such albuminuria may exist and be due to other causes; but the albuminuria of venous fulness is the steadily progressive albuminuria which marks the oncome of pronounced cardiac failure, and which is never to disappear. It may be more or less at times, fluctuating with the changes in the aspect of the case, but it is essentially steadily progressive in its nature, and indicates the downward direction of the case.

About the significance and causal relationships of this form of albuminuria there can exist, unfortunately, no doubt, and its appearance is of the worst omen. It has just been said that its amount varies from time to time with the fluctuations of the case; but where its amount remains undiminished, while the aspect of the case generally is somewhat improved, it is of very bad prognostic import. Consequently, when albumen has once shown itself, it is well to test the urine regularly in cases of cardiac dropsy, as temporary improvement is by no means rare even in cases where it can only be very transient from their nature. To sum up, then: (1) the bulk of urine is the measure of arterial fulness, and rises and falls along with it; (2) albuminuria is the measure of venous fulness, and rises and falls along therewith. Now there remains the third point to be considered,—viz., the presence of lithates in the urine. The deposit, as said before, is usually of a reddish or deep pink color, such deposit being usually composed of lithates. (But urine deposits, when of paler coler, may consist largely of phosphates in some form.) For our purpose here the main matter is to recognize the fact that the deposit is composed of lithates. When albuminoid waste matter is fully oxidized it becomes urea. Uric acid is a less completely oxidized form of waste. This dense concentrated urine, then, contains an excess of imperfectly oxidized waste. This is a matter which should be more carefully thought about than is the rule.

The liver has three functions: (1) the stowing up of glycogen (animal starch) from the grape-sugar in the portal vein; (2) the oxidation of waste and spare albuminoids; and (3) the production of bile. Beyond this the liver is intimately associated with the digestion of albuminoids,—though how we do not yet precisely know. It is with the second function of the liver we are chiefly concerned in this matter of the deposit of lithates in the urine. In cardiac failure, no matter whether the failure be due to primary mitral disease or to the decay of once hypertrophied heart-walls, the liver is gorged with venous blood. Indeed, not uncommonly the liver can be felt to pulsate with the impact of blood flowing backward through the tricuspid valves on the systole of the distended right ventricle. So gorged with venous blood, the liver is crippled functionally and cannot perform its work properly; consequently, we find imperfectly oxidized albuminoid waste in the urine. Not only that, but it exists in excess in the blood. Now, we know that when there exists an excess of nitrogenized waste in the blood, the flow through the arterioles is obstructed; such obstruction adds to the work of the heart, to the resistance the ventricle has to overcome on each systole. Consequently, to depurate the blood is to reduce the work of the heart. So relieved, the left ventricle will often regain much of its power. How, then, are we to depurate the blood? By remembering the functions of the liver! It plays an important part in the digestion of albuminoid matters, as well as oxidizing nitrogenized waste.

Now, it is well to bear in mind vividly and distinctly that when the assimilative organs are gorged with venous blood, their functional capacity is impaired, and it becomes necessary to administer easily digested food. To improve the tissues of the weakened heart is a most desirable object, but it is not obtained by cramming the patient with meat or its derivatives. The patient may be induced to swallow a quantity of meat, but it does not follow that this will improve the nutrition of the tissues. For interstitial nutrition good digestion is essential. Consequently, a meal of fish or a draught of milk, a portion of which is thoroughly and completely digested, will furnish more tissue-nutrition than a meal of beefsteak or mutton-chop no portion of which is completely digested. Further, the partially and imperfectly digested meat furnishes a large quantity of nitrogenized waste which has to be got rid of. Therefore, cruel as it may seem, mistaken, even, to the casual observer, such patients will do much better on a restricted dietary than on a liberal one. A series of most interesting and instructive cases has recently taught me the above lesson with unmistakable clearness. Some of them had previously been under men of the highest position in the profession: digitalis and iron had failed, even when accompanied by a generous dietary.

(Iron never is well assimilated when the liver is embarrassed.) But on a restricted dietary and appropriate measures they did admirably. In a number of instances there was decided enlargement of the liver; in several there was dropsy. So, keeping the lessons of physiology well in view, the dietary was made largely non-albuminous, fish and milk alone being allowed, with stewed fruit and cream- or milk-pudding. That was the first point,—viz., to reduce to a minimum the demand upon the liver. Then, to depurate the blood and relieve the liver of waste matter, a calomel- and- colocynth pill was given twice a week at bedtime; and next morning a draught of sulphate of soda with Rochelle salt in a warm infusion of gentian, containing some tincture of ginger as a carminative. This unloaded the liver and depurated the blood, with the result that the liver became markedly reduced in size. Digitalis was given also to increase the vigor of the ventricular contractions, and so to pump over more effectually the blood from the veins into the arteries. Betwixt the two the liver became not only reduced in bulk, but it recovered much of its functional power, and assimilation was more perfect. The heart recovered much of its tone, being once more fairly nourished; and, in broad terms, the cases did well and gained me no little *kudos*. In one of the cases, a very well marked one, the medical man's last report speaks of "a most marvellous recovery;" and certainly the case did admirably under this line of treatment adopted by me, first the liver being reduced in size and becoming functionally more efficient, and secondly the heart recovering its tone. Yet under digitalis and iron the case had made no progress for seven months under the charge of one of our most illustrious and able physicians. The amount of lithates, then, points to enfeeblement of the liver in its assimilative and oxidizing capacity, and their presence tells us that the dietary must be strictly regulated.

After this exposition, I venture to think, the reader will agree with me in thinking that the changes in the urine in cardiac dropsy contain a lesson of incalculable value if we will only take the trouble to learn it thoroughly. It is by this systematic survey and approach of a case remedially, both dietetically and therapeutically, that success is to be attained. Pains, infinite pains, much acquired knowledge, much individual thought and intellectual digestion of the required data, are essential to the successful treatment of such cases. But the attendant success is ample reward for all the pains taken: of that the reader may rest assured. J. MILNER FOTHERGILL.

THE death of Professor Julius Vogel, in his sixty-seventh year, is announced. He is chiefly famous for his work on the "Chemistry of the Urine."

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a conversational meeting held at the Hall of the College of Physicians, Philadelphia, December 8, 1880, Dr. John H. Packard, Vice-President of the Society, in the chair, Dr. William Pepper presented a communication (see page 295) on the "Treatment of Typhoid Fever," for which he received a vote of thanks from the Society.

DISCUSSION.

Dr. Bruen remarked that he would like to mention, in connection with the subject of diet, that the various preparations of the Health Food Company make delightful and highly-nourishing gruels for the convalescent: they may be combined with milk or given without, forming admirable substitutes for milk in many cases where milk alone disagrees with the patient.

Dr. J. M. Keating suggested the use of "albumen-water" when milk could not be obtained or was contra-indicated, as it often was. The whites of one or more eggs are dissolved in a pint or so of water, and then sweetened with glycerin and flavored with *orange-flower* water, or to suit the taste of the patient; this is given *ad libitum*, and given cold. He had seen this preparation retained when milk and beef-tea were not tolerated; it had saved a patient's life in a bad case of typhoid dysentery, and in a case that came under his care lately it was the only thing that was tolerated by a child of two years for almost two weeks. It is largely used in France; but no mention of it is to be found in any report of the treatment of typhoid fever in any of our journals or text-books.

Dr. George Hamilton said that he could not quite agree with the conclusions of the paper of the evening. He was obliged to differ with the lecturer in regard to his method of treatment, yet he could not claim to have been successful in ninety-eight per cent. of cases of typhoid fever.

He had never, in the first place, insisted upon such perfect quietude: where the patients had considerable strength he did not forbid them to use the commode, or hinder them from getting out of bed to empty the bladder and the bowels, and he had never seen any bad results attributable to this. As regards the diet, typhoid fever commences to weaken the patient from the very outset, and where the patient has an appetite for food he was inclined to listen to the voice of nature and give light nourishing food, and not so restricted as the lecturer had recommended. He would give pure, undiluted milk or well-spiced beef-tea under ordinary circumstances. He had noticed a great contrast between the practice of different physi-

cians in this disease as regards stimulants. He would in the latter prostrate stages of the disease use them, and incur some risk of future fondness for them, rather than deprive patients of their benefit when evidently needed.

Dr. Condie, a noted temperance man, often remarked that he could not get along without stimulants in certain cases of typhoid. He nearly always found turpentine emulsion useful in the latter period of the complaint, and, with laudanum, as an injection, in looseness of the bowels answers very well.

Much depends in typhoid fever upon the nursing and attention to the general treatment. Many cases will doubtless go through without any particular medication, but if at all protracted the patients become very weak, so that nourishment, as much as the patient can well take, with stimulants, is of great importance. The tendency always to prostration must be checked if possible.

The utmost attention should be given to hygiene, especially ventilation. All objects that annoy the patient should be removed from the room, especially when the patient is in a low, rambling condition; no disturbing visitors; the patient often hangs between life and death, and the slightest untoward incident may turn the scale against him.

In regard to slight hemorrhages from the bowels, he had seen them productive of benefit, but if profuse or repeated they are apt to carry off the patient. He mentioned a case where, after a large bloody evacuation, the patient had a second hemorrhage which was retained in the intestine, but proved fatal. He believed that no rule of treatment (except that of supporting the strength) could be laid down: each case must be studied by itself and so treated.

Dr. Henry H. Smith said that the treatment of typhoid by nitrate of silver had been highly praised by the late Dr. J. K. Mitchell when Professor at the Jefferson Medical College, many years ago. It fell out of use, probably because experience did not show it to have any special value.

The speaker dissented from the paper in several points, but objected particularly to the diet as laid down by the lecturer, as being too reducing.

Dr. O'Hara said that the three last cases of typhoid he had in children, although alarmingly ill as to high temperature and progressive exhaustion, partook of very little nourishment, or medicine either, and seemed to pursue a regular course, and within three to four weeks were in a state of convalescence. He had frequently seen temperatures of 105° which seemed to burn out the poison, along with the tissue-elements of the body, and he thought from his experience that alcoholic stimulants, as wine-whey or milk-punch, acted directly as refrigerants as well as nutrients. He thought that there was too much fear of the high temperatures, as in severe cases it was a part of nature's plan of getting rid of the disease. It is a self-limited disease, and we must aid nature by treating symptoms as complications; but he did not find, ordinarily, that the bowels were locally affected so much as Dr. Pepper had stated, or that he could find relief from treatment especially directed to the glandular structure of the bowels. It was not uncommon to have no irritation of the bowels, no looseness, but constipation from paralysis of the bowels, and laxatives were required through the course of the disease. He considered the worst type of the disease when the nervous system was overwhelmed from the start with the poisoned blood, the result of the zymosis. These cases afterwards gave us enteric symptoms, and he fancied that the diarrhœal condition, within limits, as well as the high temperature, was one of the manifestations essential to nature's plan of getting rid of the poisoned condition of the blood.

He believed that the worst cases were septic in their nature from the beginning, and not due to any local condition of the alimentary canal.

He thought that the want of assimilative power to digest milk was at fault when it disagreed, and that as much casein was there, diluted, as before. He thought wine-whey suitable at any time in a case of any severity, and he believd many cases would recover without any special treatment.

Dr. W. R. D. Blackwood said that he recalled a paper read some time ago which was based on the idea that a good many people are starved to death in typhoid fever, and advocated giving good food, beefsteaks, etc. That paper certainly was in contrast with the paper of the evening, showing that doctors disagree. During the early years of the war he had seen much typhoid, in Virginia, among the soldiers on the Chickahominy, and had fault found with him because some of his patients were limited to ten grains of quinine daily and received no stimulant; the custom among surgeons generally was to give a pint—and in many cases a quart—of whisky during the day. The mortality was large, and he attributed it to this abuse of stimulants.

He could not see how alcohol or immense doses of quinine could have an antipyretic effect; he had never been able to observe it in practice. Early in the campaign he had been instructed that typhoid was a mixed disease, but even on the Chickahominy it presented the same features as the typhoid met with everywhere else: the so-called typho-malaria was a myth. Moreover, he was satisfied that large doses of quinine do harm, and that opium, likewise, does harm through aggravation of brain-symptoms, when present, and he uses, therefore, hyoscyamus, or the bromides, in preference.

Diarrhœa is often kept up by curdled milk,—milk being a very concentrated food,—and it is often given without due regard to the patient's condition. In preference to mere dilution, which does not at all alter the proportion of casein, he would give wine-whey, using astringent wines where there was much tendency to diarrhœa. In septic cases he uses carbolic acid freely from the start, but had also obtained good results from salicylic acid.

He was satisfied that in fully eighty per cent. of the cases he had seen, the less medicine given the better for the patient. In many cases he uses literally no medicine, or simply a placebo, merely watching for symptoms or complications. For the diarrhœa he uses gallic and carbolic acids.

Sponging the entire body with lukewarm water is not only pleasant to the patient, but exceedingly efficacious in high temperature; but the cold bath and pack he was certain had done more harm than good, if cases were only honestly reported. He has little faith in quinine in this disease, and less in alcohol. Maltine, when there is not much tendency to diarrhœa, and the Health Food Company's preparations, are very useful. He recommended that less attention should be paid to the therapeutics and more to the diet.

Dr. Charles K. Mills said that of course the early recognition of typhoid fever had, or might have, an important practical bearing on its treatment. He was led to make this remark because he had recently seen cases of typhoid fever beginning with remarkable nervous phenomena. In one case the patient was a lady of middle age, who had for several weeks nursed a child sick with typhoid fever. She was suddenly taken down with what an alienist would probably have pronounced to be acute dementia. She would not speak, refused food entirely, and at times exhibited great excitement. She had some fever, with irregular temperature. At the end of a week the case settled down into one of typhoid fever, with the temperature record and other special manifestations. In a second case mental aberration and tetanoid symptoms were at first present. Four days after the appearance of these symptoms, however, a typhoid rash—the most abundant he had ever seen—appeared, and henceforth the disease took the usual course of the fever. A third patient had been treated by an irregular practitioner for cerebro-spinal meningitis, probably because of the presence of some spasm, or apparent spasm, of the muscles of the neck and back. He found the rash and other evidences of typhoid. The first two cases terminated favorably; the third died. All of these cases were treated at first with remedies not usually considered advisable in typhoid fever, such as chloral, the bromides, and local depletion.

Dr. Geo. B. H. Swayze said that for nearly twenty years he had been in the habit of using nitrate of silver in the treatment of typhoid fever whenever there was any considerable enteric irritation. He had attended the last course of lectures delivered by Prof. J. K. Mitchell at the Jefferson Medical College, and had never forgotten the emphasis with which Prof. Mitchell endeavored to impress on the minds of the class the value of nitrate of silver in many cases of typhoid fever. In cases where the intestinal irritation was severe, with marked tenderness and pain and persistent evacuations, Dr. Swayze had found no treatment so satisfactory as the use of nitrate of silver. In such cases he employed it in powder, finely rubbed with subnitrate of bismuth and opium,—from one-sixth to one-fourth of a grain of nitrate of silver to one-half or one grain of opium (according to the degree of pain), and about five grains of subnitrate of bismuth, for each dose, repeated three or four times a day, if necessary. If the patient could not take powders, he employed it in solution, in combination with deodorized tincture of opium. He does not now recollect losing more than three or four cases of typhoid fever in an experience of twenty years. He would recite the case of a lady, eighty-six years old, who had just recovered from a remarkably severe attack of typhoid fever, attended with distressing irritation of the bowels, the discharges proving unusually persistent, often numbering from nine to fifteen movements per day, and many also during the night. Astringents had no effect in relieving her until he used the nitrate of silver. Some years ago, typhoid fever entered his own family; his three sons were ill with it, two at the same time. They were ordered liberal doses of quinine at the outset, but grew steadily worse, until it became evident they had typhoid. The symptoms of the oldest boy became extremely grave. Febrifuges seemed useless, and appeared only to aggravate the diarrhœa. The epistaxis was distressing, the alvine evacuations were frequent, and often so sudden that the bedding had to be changed. For several days he lay with his knees drawn up, in consequence of intestinal soreness and tympanites. His feet became cold and purple. The physician who occasionally saw him thought he must die. In his perplexity Dr. Swayze recalled Prof. Mitchell's treatment of nitrate of silver, combined it with the bismuth and opium, and in twenty-four hours the case was better. The feet were kept warm with hot bricks, turpentine was freely applied upon the abdomen; he began to take nourishment; with the relief of the bowels the gravity of the other symptoms rapidly abated, a liberal use of whisky was allowed, and any nutritious food he could be induced to take was given. The result was that he recovered, and his father believes his life was saved through the remedial agencies of nitrate of silver, liberal stimulation, and nutritious food.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, DECEMBER 13, 1880.

THE PRESIDENT, Dr. S. W. GROSS, in the chair.

Case of phthisis and tuberculosis—Enormous cavity—Physical signs of pneumothorax. Presented by DR. J. H. MUSSER.

W. M., æt. 25, admitted to University Hospital, September 13, 1880; native and resident of Philadelphia; ornamental japanner; spree occasionally; used considerable tobacco; had gonorrhœa; thinks his "breakdown" due to venereal excess in youth; single; a brother living; two sisters died when children; mother living; all his brothers and sisters died of consumption; history of father's family not known; always healthy; present trouble dates back fifteen months; subject always to a slight winter cough. In July, 1879, was overheated; cooled suddenly, causing a chill, followed by a pain in the head and breast, and a cough with frothy expectoration; no blood. In two weeks, on account of cough, pain in the left lung, and debility, had to quit work; soon resumed work, and in a short time lost appetite; had fever and night-sweats; cough grew worse, expectoration more purulent; became weaker and weaker; worked all winter, but in March had to give up; never went to bed until he entered hospital; all spring was very weak; throughout summer, with the cough and hectic, had diarrhœa; two or three passages a day, without pain, not fetid, sometimes dark, again green; late in summer indigestion and vomiting ensued.

When admitted, was very feeble and very much emaciated; pale, anæmic face, brown hair, blue eyes, not long lashes; pearly sclerotics and pale conjunctivæ; countenance of anguish; skin moist, fingers slightly clubbed; fever and night-sweats; appetite poor, capricious; tongue slightly coated all over, not flabby; weight and fulness after meals, flatulence, poor digestion; bowels constipated; hemorrhoids; at intervals slight abdominal pains; liver extends one inch below ribs; spleen not enlarged; very slight expansion of left lung; vocal fremitus absent anteriorly and laterally; at base slightly increased, anteriorly and posteriorly amphoric voice, at the base increased vocal resonance; on percussion, upper lobe tympanitic; lower lobe, in front, at the side, and behind, dulness; upper lobe on auscultation pure amphoric breathing; absent respiratory murmur; a few crackling râles on inspiration, heard over lower lobe; right lung at apex and base expanding very much; vocal fremitus normal at apex and lessened at base; vocal resonance the same.

Vesiculo-tympanitic percussion-note. At apex, front and back, prolonged expiration, harsh respiration, and a few mucous râles; puerile respiration over remainder of lung. Apex of heart in sixth interspace, one and one-half inches inside of nipple-line; impulse feeble; valvular element of first sound distinct; pulse rapid, feeble, compressible; urine normal.

From date of above note to October 17, strength failed more and more. The physical signs continued about the same. At times there were more râles at the right apex than at other times. The chest-pains increased, the right abdominal pains continued, the cough became more harassing, the hectic increased, the pulse was very rapid. On the 17th he complained of pain in the right side, and apparently friction râles were heard; the expectoration was streaked with blood. The morning of the 20th hemorrhage began, continuing an hour. During that time a pint and a half of bright arterial blood was raised, in mouthfuls, without effort. On auscultation, large bubbling râles were heard at the base of the lung; amphoric breathing and metallic râles over the cavity; very weak, pulse 134, hurried shallow breathing.

October 20.—Since last note, has been expectorating currant-jelly clots at intervals; cough very severe; diarrhœa; feels easier. At 11.30 A.M., after above note, suddenly, without cause, profuse discharge of blood from mouth and nose; death in about five minutes.

Post-mortem.—Examination four hours after death, by Dr. W. E. Hughes.

Skin yellowish. Epidermis scaling off in large flakes on the abdomen. Body much emaciated. No *rigor mortis*. Nostrils and mouth contained clots of blood.

On section, tissues dry and pale, very little blood exuding from the cut surface. Scarcely any fat. Muscles pale red.

Thorax.—Pericardium contained half an ounce of straw-colored fluid. Heart normal size, muscle not fatty to the naked eye. Right ventricle and auricle contained a chicken-fat clot. All the valves stood the hydrostatic test. The aortic valves were thickened slightly, as were also the mitral leaflets. In the latter were a few small calcareous deposits.

At the apex of the right lung a few pleural adhesions. Entire visceral and parietal layers of the left pleura firmly united and thickened, save in the lateral region. In this area, over the lower lobe, a sac was formed an inch deep, three inches wide, and four inches longitudinally, containing a few ounces of fluid with some lymph. The upper lobe of the right lung was partially solidified. On section, two small cavities, the largest an inch in diameter, both filled with a gray grumous fluid, occupied the centre of the solidification. The consolidated portion was of a gray color, with numerous small cheesy points in it. In the lower lobe there were numerous small masses of tubercle. Remainder of lung emphysematous. The vesicular tissue of the upper lobe of the left lung was entirely destroyed. The

walls of the cavity were formed of the thickened pleura, while across it extended thickened cords and bands containing the remains of obliterated vessels and bronchi. Numerous stumps projected from the sides of the cavity, and on its walls were studded small cheesy masses. The cavity was filled with blood and some puriform matter. The lower lobe was consolidated. Numerous cheesy masses and a few cavities were found in the gray consolidation. The bleeding-point of the hemorrhage was in one of these cavities. The edges of the lower lobe were lobulated, apparently congenital.

Abdominal cavity.—It contained a pint and a half of straw-colored fluid. Intestines presented externally, at varying intervals, dark-red blotches. Liver weighed four and a half pounds; pale and fatty, slightly cirrhotic at lower edges. Gall-bladder contained a little bile. Spleen weighed twelve ounces; was soft; dark red in color. Kidneys weighed ten ounces each. They were fatty; capsule not adherent. Stomach at largest part only one and a half inches in diameter. Rugæ very prominent. Mucous membrane very pale. A small circular ulcer with raised indurated edges in the duodenum, four inches from the pylorus. Two similar ulcers in the jejunum. All the upper Peyer's patches ulcerated, only very slightly, as if just beginning; some of the patches had two or three transverse excavations. The lower patches were elevated and rough, as if tubercle had just developed. In the cæcum numerous small ulcers similar to those in the intestine. Less numerous in the ascending and absent in the transverse colon. Mesenteric glands not enlarged.

Brain healthy. Slight increase of arachnoid fluid.

On account of the physical signs presented during life, the mode of death, and the extensive cavity found after death, the case is of interest. The physical signs of consolidation and cavity of the right lung were masked by the compensatory emphysema. The signs of the cavity of the left lung were so like those of pneumothorax that its occurrence was considered.

Death from hemorrhage is rare in phthisis. It is of interest to note that the bleeding did not take place in the large cavity, but from a vessel in one of the small cavities in the lower lobe.

Soft fibroma of uterus. Exhibited by Dr. H. F. Formad.

I obtained this specimen and the history of the case through the kindness of Dr. S. A. S. Jessop, of the Philadelphia Hospital, from a case in his private practice in Armstrong County, Pennsylvania.

Mrs. A. C., aged 30, has been confined nine times; only one child living; the rest were either still-born or died during delivery. Owing to a malformation of the pelvis, forceps were always used.

In the summer of 1880 she was last delivered of a still-born child. After the removal of the placenta the doctor made an examination, and discovered a tumor attached loosely to the mucous membrane of the uterus, which by gentle traction was easily removed. Hemorrhage was profuse; the contraction of the uterus did not take place for hours, and then only after administration of enormous doses of ergot.

The patient subsequently recovered and regained perfect health.

The tumor was lobulated, had a distinct capsule, and measured about six inches in its largest diameter; in some parts it was deep red in color, and was of elastic, moderately hard consistence.

Microscopic examination showed the tumor to be made up exclusively of areolar connective tissue, with large areas infiltrated with blood. Portions of the growth not infiltrated with blood showed a beautiful mesh-work formed by stellate cells, densely packed in some places, in others forming a loose mesh-work with prominent nuclei at the nodal points. Bands of fibrillar tissue were scarce, forming in places a concentric arrangement around blood-vessels. These appearances lead to the diagnosis of a *true soft fibroma.*

Hairy papilloma of conjunctiva. Presented by Dr. H. C. Boenning.

This eye was presented to me four weeks ago by a butcher, who regarded it as a great curiosity. While purchasing cattle at the drove-yard, the attention of the gentleman referred to was called to a strange appearance of the right eye of a steer a short distance from the beeves he had selected. Upon closer examination, a hairy tumor was seen protruding through the palpebral fissure. The growth was carefully examined by the cattle-dealers and butchers present, who annually see many thousands of cattle, and all concurred that they had never seen anything of the kind before. The animal was purchased, killed, and the eye brought to me, the gentleman stating that, though the growth was touched with a skewer while the animal was still on the hoof, it did not seem to possess any sensibility, the animal remaining motionless. The hand was also waved to the right of the beast below the level of the eyes without any recognition on the part of the steer; the same motions, when brought within the limits of vision, occasioned turning of the head and an effort to evade the threatened blow. The fresh specimen presented the following appearances. Over the lower, outer portion of the cornea, extending slightly upon the sclerotic, was an ovoid, reddish growth covered with hair of the same color. The growth occupied an area of about a silver dime, was firm in feel, and creaked when cut. It extended from near the centre of the cornea to a few lines beyond the insertion of the cornea, was about seven lines in di-

ameter, and encircled by a groove of, probably, retracted tissue, this separating a rim of tissue identical with the rest of the morbid structure. A vertical section demonstrated to the naked eye its conjunctival origin. The tumor did not infringe upon the cornea or sclerotic proper. At least one hundred hairs grew from the tumor; some of them were seven lines in length, the remainder varying from three to five lines in length. Section of the fresh specimen showed a moderate amount of epithelium, the rete poorly developed and the papillæ small, though larger, I think, than shown in the sections kindly made by Dr. Longstreth this morning after about one month's maceration in alcohol. The subpapillary layers were composed of dense fibrous tissue containing numerous hair-follicles, each containing a non-medullated hair. Numerous sebaceous follicles existed, their ducts emptying both on the surface of the growth and into the follicles. No nerves were visible. This tumor was doubtless congenital. The histogenesis is interesting. The conjunctiva overlying the cornea is without papillæ; hence the impossibility of such a growth containing some of the elements of true skin developing after birth. I might mention that no attachments existed between the tumor and the eyelids.

REVIEWS AND BOOK NOTICES.

How to Use the Forceps. With an Introductory Account of the Female Pelvis and of the Mechanism of Delivery. By Henry G. Landis, A.M., M.D., Professor of Obstetrics and Diseases of Women and Children in Starling Medical College. New York, E. B. Treat, 1880. 12mo, pp. 168.

One would suppose that in such a monogram special mention would be made of those instruments meeting with most favor from the profession; but the entire subject is dismissed in a very summary manner by the author saying that he prefers the Davis forceps, and for reasons, it may be said, not very conclusive, although the value of that instrument ought not to be underrated. The claims of the Hodge and Simpson forceps, so generally used in this country and in Europe, are not even alluded to.

Of the straight forceps he says, "I say nothing, because it is nearly obsolete, and every text-book bears witness against it." There are some eminent teachers of obstetrics, here and abroad, who still carry and use it, as well as the double-curved forceps, and the author should be aware of the fact that it is very extensively used in Great Britain and Ireland, and that the text-books of that very respectable quarter of the medical world are unanimous in according to it all that its friends claim for it.

In his directions for applying the instrument he is no less dogmatic than in asserting the claims of the Davis forceps. He says that the blades should and can be applied in the bi-parietal diameter *at the superior strait*, ignoring the fact which he mentions on page 112, that Dewees, Meigs, and Hodge "admitted exceptions," and that Dr. Davis himself, whose forceps he uses, "was sometimes unable to introduce the second blade of his forceps upon the right side of the head." Dr. Meigs always preferred the same instrument, but says that in some instances the application of the second blade "is found to be difficult, dangerous, or impossible." The author says, "I utterly deny even the difficulty of application in the normal pelvis." He evidently fails to see that he is attacking an opinion now obsolete,—viz., that the forceps is to be applied with *exclusive* reference to the *sides of the pelvis;* hence, in the heat of his argument he asserts that it should and *can* be applied strictly to the sides of the head only.

The author says that "pushing, not pulling, is the first step in traction," recognizing here the principle invoked in the Tarnier forceps, which he characterizes as "an unnecessarily ingenious contrivance." He advises pressure on the blades between the lock and the extremity, so as to push the head toward the outlet, the hand making the pressure being a fulcrum and centre around which the blades revolve. The diagram on page 125, which is said to represent "the forceps applied to the head at the inlet," indicates a very unusual position,—viz., occipito-pubic.

Speaking of compression, he says "the bi-parietal diameter is capable of being diminished by their use [the forceps] from a half-inch to an inch." He does not explain how the Davis forceps, which he uses, can produce a compression of one inch. The distance between the blades of that instrument is two and seven-eighths inches, between which and three and one-half inches, the bi-parietal diameter, is a difference of only five-eighths of an inch.

The author unqualifiedly condemns all leverage or oscillatory movement, but attempts little argument, leaving almost the entire *onus probandi* with Matthews Duncan and Albert Smith. Here he does Robert Barnes the injustice of saying that he recommends leverage "without traction." His assertion on page 93, that "any use of the forceps which implies leverage upon the sides of the obstetric canal is unscientific, dangerous, and criminal," is certainly vigorous enough to express his meaning. Certain it is that very many gentlemen make leverage movements who are considered by the mass of the profession to be *scientific, safe*, and the very reverse of *criminal*. G. W. L.

A Practical Treatise on Diseases of the Skin. By Louis A. Duhring, M.D., Professor of Diseases of the Skin in the Hospital of the University of Pennsylvania, etc. Second Edition, Revised and Enlarged. Philadelphia, J. B. Lippincott & Co., 1881. Octavo, pp. 644.

The first edition of Professor Duhring's treatise has been out of print for nearly a year, during which time its author has been engaged actively in the preparation of the present revised and enlarged one. At the time of its first issue the work was the best, take it all in all, which had up to that time been brought out on the subject of which it treated. The minute and painstaking care with which it was elaborated, and the equal balancing of one subject with another so that each should have its due share of attention and treatment, gave it a unity of finish deserving the highest praise; and the clearness and beauty of its style, the lucid definitions, the ample yet simple details of treatment, and the pains with which all the rubbish and lumber of the older dermatology were swept aside and consigned to oblivion without the loss of any essential fact or observation, showed the hand of the master. We do not hesitate to say that the first edition of Professor Duhring's treatise was an "epoch-making" work, and that since it appeared the study of dermatology has ceased to be the bugbear which it once was, and that both the teaching and the study of this interesting and important branch of medical science have proceeded on a more satisfactory basis than could before have been thought possible.

Most writers would have rested satisfied with this, and in a second edition, coming so soon after the first, would have contented themselves with putting in a little padding here and there and writing a fresh preface. A careful examination of the work before us and a comparison with the first edition show that the course pursued by Professor Duhring has been very different from this. From the preface we learn that entirely new articles have been written on many subjects, while others of importance which were treated of in the first edition have been largely rewritten and added to in this. The fact is, however, that almost every page in the entire book has been revised, retouched, and improved, in accordance with the constantly changing and enlarging area of our knowledge of the various diseases of the skin. Extensive additions have been made, especially in the subject of treatment, and this has been brought up fully to the level of the most advanced practical stand-point of to-day. The last five years have comprised a period of great activity among the dermatologists of this country, and it may, perhaps, be asserted that, outside of the region of mere pathological and microscopical research, more has been done here than in any other country during this period. This fact finds ample acknowledgment in the pages of Professor Duhring's book, and it is a true exponent of the American dermatology of to-day. This brings us to a pleasing feature of the work, with the mention of which we must close this necessarily brief notice.

No one who has done good work in dermatology is slighted. With judicial fairness Professor Duhring sees something good in each contribution to knowledge, and does not exalt his own work or that of his friends at the expense of ignoring that of outsiders. This cordial recognition of others is everywhere observable.

In conclusion, let us say that the book is *totus, teres atque rotundus*,—complete, well rounded, thoroughly elaborated,—a work of which the profession of this city and country may be proud. V. H.

Food for the Invalid, the Convalescent, the Dyspeptic, and the Gouty. By J. Milner Fothergill, M.D., and H. C. Wood, M.D. New York, Macmillan & Co., 1881.

The conception of this little book originated with the well-known London correspondent of the *Philadelphia Medical Times*, but, as it seemed best that it should represent the resources of the American as well as of the English "sick kitchen," Dr. Wood was associated in its preparation. The somewhat lengthy introduction is a concise, very practical dissertation on diet, whose style seems to us so like that of Dr. Fothergill that we opine he wrote most of it. Moreover, we cannot find any patches: if put in at all, the sewing is very neat and the patch well matched.

The body of the book is occupied by a large number of receipts, all of which have been carefully tested, and which in their variety afford a wide range of diet. Some of them—*i.e.*, goose-pudding—are rather strong for a sick stomach less capacious and well trained when in health than is that which ministers to the two hundred and eighty pounds of its genial North-of-England endorser. These three hundred receipts afford, however, an abundance of delicate dishes, and, as Dr. Fothergill suggests, the book may be useful to the physician who marks with pencil upon its pages such food as he thinks the individual patient owning the book may with safety use.

Medical and Surgical Electricity. By George M. Beard, A.M., M.D., and A. D. Rockwell, A.M., M.D. Third Edition, Revised by A. D. Rockwell, M.D. New York, William Wood & Co., 1881.

This edition preserves in all respects the peculiarities of the earlier ones. The book has been chiefly modified in those chapters treating on Diseases of Women, The Sequelæ

of Acute Diseases, Exophthalmic Goitre, and Electricity in Diagnosis.

We see no reason to modify the opinion expressed about it six years ago.

ON CERTAIN CONDITIONS OF NERVOUS DERANGEMENT, SOMNAMBULENCE, HYPNOTISM, HYSTERIA, etc. By WILLIAM A. HAMMOND, M.D. New York, G. P. Putnam's Sons.

This book is practically a second edition of Dr. Hammond's popular treatise upon hysteria, some time since out of print. It belongs to the growing class of "pot-boilers,"—*i.e.*, medical treatises written for the laity for very practical purposes. The chapter on hypnotism, we believe, is an addition.

GLEANINGS FROM EXCHANGES.

TRANSFUSION FOR PERNICIOUS ANÆMIA—TYPHOID FEVER AS A SEQUELA IN PATIENT AND DONOR.—Dr. Charles Cary (*Buffalo Med. and Surg. Jour.*, January, 1881) reports the case of a widow of 22 admitted to the hospital under his care with marked anæmia. The tissues were firm and natural, and the body well rounded. The patient complained of dizziness on standing, and of frequent and severe epistaxis. On admission the patient had a slight chilliness in the morning, with a temperature of 102° F. in the evening. There was some leucorrhœa, with pain in the left iliac fossa, but not enough uterine disease was discovered to account for the intense anæmia. The patient was placed upon a ferruginous tonic with an abundance of food, but in spite of a good appetite failed rapidly, at the end of about two weeks being nearly dead; pulse 117, hardly appreciable; temperature 101°; involuntary micturition and marked cerebral failure. The patient was utterly blanched; not even a minute vessel could be discovered in the conjunctiva. Under these circumstances transfusion was decided upon.

The operation was conducted in the following manner. The patient's left median basilic vein was exposed by dissection, and Moore's transfusion canula was inserted and allowed to remain, being held in place by rubber bands passed around the arm. The donor's left median basilic vein was then exposed and raised, a band having been placed around the arm to produce venous engorgement. Up to this point matters were conducted slowly, for there was not a drop of blood drawn, and no special pain was experienced by the patient. Everything now being in readiness, Dieulafoy's aspirator was used, being submerged in water to prevent the ingress of air, which was perhaps an unnecessary precaution. An incision was then made in the vein of the donor, and a blunt canula the full size of the vein introduced; the aspirator was thus readily filled with rich blood; its action was then reversed, but the tube from it was not connected with the canula in the recipient's arm until the blood flowed from it. Immediately upon the appearance of blood at the distal end of the tube it was connected with the canula already *in situ*, and the blood injected into the recipient's veins. The quantity thus introduced was ℥ij.

The immediate effect upon the patient of this small quantity of blood was most surprising: she felt a warm sensation, a tremor passed over her, she gave a slight convulsive movement, her face flushed perceptibly, and the operation was completed, occupying twenty seconds from the time the donor's vein was opened to the withdrawing of the bayonet trocar of Moore's canula. Two hours after the operation the patient experienced what generally follows the transfusion of blood after prolonged exsanguinity,—viz., a chill, followed by a fever which reached 103.5°.

From this time the patient's convalescence was rapid. She was troubled for a time with deep-seated and violent pain in the hepatic region, the nature of which was not determined. After the patient had been up three weeks and four days from the operation, and when she was almost ready to be discharged, she was seized with general malaise, followed by typhoid fever, running about thirty days, with a morning temperature of about 102.5° and evening temperature of 104° to (on two occasions) 105°. The anæmia did not return even during the fever. A very curious fact was that the donor was also seized with typhoid fever on the same day as the patient, the disease running about the same course.

TRANSFUSION WITH ANTISEPTIC PRECAUTIONS.—Dr. MacEwen (*London Lancet; Buffalo Med. and Surg. Jour.*, December, 1880) gives the case of a man who had lost much blood after an operation for lithotomy, and in whom transfusion was performed as follows. The patient's arm was held well up, so as to empty it of any blood which it might contain. It was also maintained considerably above the level of the patient's body, for three reasons: first, to facilitate the flow of the transfused blood into the trunk; secondly, to prevent the entrance of air into the body, as the syringe would, with the arm in this position, be necessarily held perpendicularly, with the nozzle downwards, and all contained air would remain at the top of the instrument; and thirdly, to enable any air to escape which might be in the space intervening between the opening in the vein and the occluding finger of the assistant on the proximal side. The vein was then opened. Then phlebotomy was performed on a healthy man, the blood being received into a small warm carbolized vessel, from which it was at once drawn into a warm carbolized three-ounce syringe having a narrow nozzle. When full,

it was inverted and the piston pressed, so as to expel any air, and the nozzle was then introduced into the vein. A quantity of blood was first injected into the space in the vein between the occluding finger on the proximal side and the opening in the vein itself. When this was done, the pressure on the proximal side was removed, and the contents of the syringe were slowly injected until only a couple of drachms remained. The pressure of the assistant's finger was again applied, and the syringe removed. It was then washed in 1 to 80 carbolized watery solution, recharged, and the blood introduced as before. The tin into which the blood flowed was kept free from clot, and several times a fresh cup was substituted. The arm from which the blood was drawn, and that into which it was injected, were kept constantly under the spray, and the blood itself, from the time it left the one arm until it was injected into the other, was either exposed to the carbolized spray or in contact with carbolized instruments: so that the whole transfusion was thoroughly antiseptic. With the exception of the transfusion being performed antiseptically, the other details of the operation were nearly the same as those adopted by Mr. Lister in a case in which he performed transfusion. The patient recovered completely.

MISCELLANY.

RUSKIN ON COOKERY.—Mr. Ruskin takes no mean view of the dignity of the cook's function. "What," he asks, "does 'cookery' mean? It means the knowledge of Medea, and of Circe, and of Calypso, and of Helen, and of Rebekah, and of the Queen of Sheba. It means knowledge of all herbs, and fruits, and balms, and spices, and of all that is healing and sweet in fields and groves, and savory in meal; it means carefulness, and inventiveness, and watchfulness, and willingness, and readiness of appliances; it means the economy of your great-grandmothers, and the science of modern chemists; it means much testing and no wasting; it means English thoroughness, and French art, and Arabian hospitality; and it means, in fine, that you are to be perfectly and always 'ladies,' 'loaf-givers;' and as you are to see, imperatively, that everybody has something pretty to put on, so you are to see, yet more imperatively, that everybody has something nice to eat."

ON THE DIGESTIVE POWER OF FIGS.—In the *Comptes-Rendus*, xci., Professor Bouchut speaks of some experiments he has made going to show that the milky juice of the fig-tree possesses a fermentative power of a digestive character. Having mixed some of it with a preparation from animal tissue, he found the latter well preserved at the end of a month. This fact, when brought into connection with Professor Billroth's case of cancer of the breast, which was so excessively foul-smelling that all his deodorizers failed, but in which, on applying a poultice made of dried figs cooked in milk, the previously unbearable odor was entirely done away with, gives an importance to this homely remedy not to be denied.—*Medical Press and Circular.*

TREATMENT OF PAINFUL CALLUS.—Professor Gosselin, of Paris, observes that when the pains which have their seat in the callus of a fracture are of a neuralgic origin we should treat them by blisters or cutaneous revulsives, and especially by the tincture of iodine. Hot or cold douches, or sulphurous douches, or frictions with a chloroform liniment may also be had recourse to. Finally, a roll-bandage with wadding is of undoubted utility, diminishing the pain sensibly by saving the limb from the little shocks which keep up the painful condition.—*Medical Press and Circular.*

CURE OF EPISTAXIS OCCURRING IN CIRRHOSIS OF THE LIVER.—Dr. Verneuil reports a case in which epistaxis occurring in cirrhosis of the liver, and which ergot and digitalis failed to arrest, was stopped by a fly-blister over the hepatic region.

DR. JOHN CURWIN, late Physician in Charge of the State Lunatic Asylum at Harrisburg, has established himself in the latter city as a specialist in mental disorders and diseases of the nervous system.

DR. WILLIAM LAUDER LINDSAY, author of "Mind in the Lower Animals in Health and Disease," died in Edinburgh recently, aged 50 years.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM JANUARY 23 TO FEBRUARY 5, 1881.

VOLLUM, E. P., MAJOR AND SURGEON.—Granted leave of absence for six months on Surgeon's certificate of disability, with permission to go beyond sea. S. O. 24, A. G. O., January 31, 1881.

GREENLEAF, C. R., MAJOR AND SURGEON.—His leave of absence, granted him in S. O. 158, series 1880, from A. G. O., extended to May 1, 1881. S. O. 20, A. G. O., January 26, 1881.

WILLIAMS, J. W., MAJOR AND SURGEON.—Par. 9, S. O. 2, c. s., A. G. O., relating to him, is revoked. S. O. 20, c. s., A. G. O.

BENTLEY, E., MAJOR AND SURGEON.—Announced as Acting Medical Director of the Department until the arrival of a medical officer his senior. G. O. 2, Department of Arkansas, January 17, 1881.

TAYLOR, B. D., CAPTAIN AND ASSISTANT-SURGEON.—The operation of par. 4, S. O. 14, c. s., A. G. O., as far as it relates to him, suspended until March 1, 1881. S. O. 20, c. s., A. G. O.

GARDINER, J. De B. W., CAPTAIN AND ASSISTANT-SURGEON.—Relieved from duty at Camp Huachuca, and assigned to duty at Fort Mojave, A. T. S. O. 7, Department of Arizona, January 15, 1881.

BURTON, H. G., FIRST-LIEUTENANT AND ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Niagara, N.Y. S. O. 18, Department of the East, February 1, 1881.

PHILADELPHIA, FEBRUARY 26, 1881.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON HYSTERO-EPILEPSY AND HYSTERICAL RHYTHMICAL CHOREA.

Delivered in the Hospital of the University of Pennsylvania, January 14, 1881,

BY H. C. WOOD, M.D.,

Clinical Professor of Nervous Diseases, etc.

Reported by Dr. CHARLES K. MILLS, Chief of Nervous Clinic.

THE patient is a girl nearly 17 years old. Her mother is living and well. Her father died fifteen years ago after a "paralytic stroke." She has brothers living and in good health. Four brothers are dead: two died of consumption, one of intussusception, and the fourth was drowned. The girl was well until she was thirteen years of age. She was then attending public school, was bright of mind, and was growing fast. She began to complain of being tired and of "lumps in her throat," and became afflicted with a low whining or barking cough, which lasted fully six months. It would come on about twelve o'clock every day and last until four the next morning, when she would go to sleep. This periodicity remained as long as the cough lasted. One day the cough left her, and immediately she began to have peculiar movements of her limbs, from which she has suffered ever since.

The following description may serve to convey an idea of their character. She lies in bed propped half up with pillows. Her forearms are held flexed on her arms at an angle of a little less than 90°, one hand usually near to or loosely thrown over the other. Her thighs are flexed on the pelvis at an angle of about 160°, and the legs on the thighs at an angle of 110°. The limbs, held by clonic spasm in this position, are in a state of constant rhythmical vibratory movement. The forearms move up and down over a limited area, with the hands moving inwards and slightly rotating towards the body. The thighs vibrate inwards and outwards, so that the knees sometimes strike together. The movements of the upper and lower extremities are in unison. At a number of counts they were from 110 to 120 per minute, and the knees at each vibration moving about three inches.

During sleep the movements are stilled. It is a curious fact that before coming into the hospital she has, as a rule, gone to sleep about four in the morning, sleeping until ten or twelve o'clock, and then again beginning with the movements, just as at the first she had the cough coming and going at regular intervals.

Three months before the nervous cough came on she menstruated imperfectly, but has never since had any molimen. She is a Catholic, and is religiously inclined, but has not been under any remarkable religious excitement. She has had numerous hysterical manifestations, such as spells of laughing, crying, irritability, etc.

She has been very persistently treated before coming to the hospital. During the last year she was under the care of Drs. Charles Wirgman and M. O'Hara, with Dr. Charles K. Mills as consultant. These gentlemen sent her to the hospital, hoping that therapeutic measures might be more efficient if she was removed from her home surroundings.

These are the main points in the history of this curious and unusual case. Other facts of interest will be brought out as we proceed with the examination of the patient and the discussion of her symptoms. Observe her closely. Her back is much curved; she seems unable long to hold her trunk erect without support. The muscles of the back are weak. She has the hysterical face. She constantly casts her eyes downwards. The rhythmical movements which I have described continue ceaselessly. The limbs are strongly flexed. They can, by the exertion of great force, be straightened, but the contractures at once return. When she is watched without her knowledge, the contractures remain and the movement continues, the latter, however, being usually a little more violent when she is under observation. Testing for the skin and patellar reflexes, they are found to be noticeably diminished. She is not wasted. Electro-contractility is retained.

Below the knees, as I show you, we have marked anæsthesia both to the æsthesiometer and to electricity. She does not recognize the difference between ice-cold and hot water. We have loss of sensibility as regards touch, pain, and temperature.

The anæsthesia extends to the deeper parts,—to the muscles. In the thighs it is incomplete. In the arms we have also partial anæsthesia. In reported cases of a somewhat similar character the special senses have been more or less affected. So far as we have been able to discover, no disturbance of any of the special senses has occurred.

Where does this case belong? Evidently in some of the groups of hysteria. The girl, according to her statements, has had violent epileptiform attacks. At one time during the last two years the convulsions were quite frequent. But at present she cannot be considered an hystero-epileptic. Those of you who have attended these clinics regularly will do well to contrast the present case with that of Mrs. S., who was in our wards a few months since. Like almost all the hystero-epileptics that I have seen, she was a fat woman, afflicted to some extent with apepsia and constipation, but by no means badly nourished. Her attacks were usually near the time of menstruation, were very violent, and were mostly preceded by some form of gastric distress. I read from notes made upon her case by Dr. Musser, our registrar:

"When she entered the ward, heart and lungs normal. She had left-sided paralysis and anæsthesia, the tongue turning to the left. The face not paralyzed. This state followed the last convulsion. Since then she has also been having headaches. After every severe convulsion she has loss of power and of sensation of some part of the body,—a leg or an arm,—which disappears gradually or another convulsion removes it. Pressure on the ovary does not influence the convulsions, nor is there any ovarian pain or tenderness. Muscles relaxed; electro-muscular contractility good.

"In the attack, without warning or after the gastric symptoms previously noted, she would fall to the floor with tonic spasm of the muscles of the neck, the trunk, and the limbs. In a few seconds clonic spasms followed the tonic, while the respiration would be stertorous, and there would be frothing at the mouth. Consciousness would be lost with the recurrence of the tonic spasm. Sometimes this epileptiform stage, lasting from two to ten minutes, would be followed by a trance-like state, the muscles all being relaxed, the breathing scarcely perceptible, the head turned to one side, the eyes closed. Often she would languidly open her eyes when spoken to or when pinched, or would give a moan, or would recognize nothing. The pupils were never dilated; the conjunctivæ sensible. Convulsive movements would often recur in the trance, which lasted from one to six hours. In about twelve or fifteen attacks, after the epileptiform seizures, tonic rigidity of the muscles of the body produced persistent opisthotonus. This stage continued a few minutes, followed by relaxation, exhaustion, and often fits of sobbing. Either a sleep from exhaustion or a fit of crying ended the attacks. During the opisthotonic stage the head would be buried into the pillow with a boring motion. After five of the severe attacks left hemiplegia and hemi-anæsthesia followed, lasting from a day to two weeks.

"Often the epileptiform seizures would be followed by slight exhaustion, from which in half an hour she would have recovered.

"Iodide of potassium was given and iodism produced, but no relief. The iodic eruption was all over the body, consisting of large, red, slightly-elevated blotches, tender and disappearing on pressure. Bromide of potassium was also given. After a violent convulsion all paralysis disappeared, and, being tired of hospital life, she was discharged.

"Some months later she returned to the hospital. Again had paralysis of left side. While in ward had one or two convulsions. Fluid extract ergot, ℥ss ter die, and monobromide camphor every four hours, gave her relief. She became pregnant just before entering the house. Whether the treatment or the pregnancy relieved her is a question. At all events, the return of the convulsions at longer intervals and the abatement of their violence was the result."

Subsequently to leaving the hospital Mrs. S. became the private patient of Dr. Musser, who gives the following account of her after-history:

"During the time of carrying child, in the first month had one hystero-epileptic attack. The three months following, had slight hysterical attacks. The last five months, had an attack (severe) of lumbo-abdominal neuralgia and of hysterical aphonia. For two weeks previous to labor suffered extremely from lumbo-abdominal pain. Twice had hysterical faints, but no convulsions. The labor was not difficult,

and was without exhaustion. About three weeks after the birth she had two brief attacks of unconsciousness, but no spasms."

It is plain that at present the case before us separates itself from such hysterical forms as were present in Mrs. S., but conforms very closely with the affection which is described by Charcot under the name of "hysterical rhythmical chorea." The physiology of such a case as this is to me a very extraordinary one. We are apt to have the idea of simulation connected with hysteria. Emotional disturbance certainly always is; but true simulation only occasionally. Ordinary chorea minor, or St. Vitus's dance, may be produced by fright from a thunderstorm or other cause. I have seen it so developed at once. Yet we do not think it simulated. Faith, fear, or other emotion will sometimes cure these cases of intensest hysteria; but this does not prove that the spasm or paralysis is a simulated phenomenon. Lie on your backs and move your legs, as this girl does, eighty times a minute backward and forward, and how long do you think that your muscular powers will suffice? Possibly twenty minutes, probably only ten. This continuous, untiring effort is one of the most extraordinary phenomena of these cases. The muscles of organic life work untiringly, continuously; but it is only in these diseased conditions that muscles of voluntary movement take on such attributes. This girl complains of no tire. An interesting point about the present case is that violent fear failed to arrest the movements. A neighbor's house was on fire; the smoke poured into this girl's chamber until there was danger of suffocation; she covered her head with the bedclothes, and the vibrations went on; her tonic spasms never relaxed. She was helpless, and seemingly would have burned alive if the conflagration had not been arrested.

Again, what is the nature of the lesions in cases like these? How can we explain the helplessness, how the vibratory movements, how the anæsthesia? I cannot answer you with any positiveness. We know only that loss of power is not always palsy, loss of sensation not always anæsthesia; or, to explain this seeming paradox, you may have loss of power, or loss of sensation, without destruction of the so-called centres or conducting tracts for motion or sensation. Let me recall here some of the experiments of Brown-Séquard. A semi-section of the cord is made; anæsthesia is produced. Another section, lower down, causes it to disappear. A section of nerve-fibres is made near one of the cerebral ganglia, and palsy results; but on division of the pons below, the palsy passes away. Cutting the sciatic, again, causes paralysis of sensation on the opposite side. The explanation of such experiments is, that centres are inhibited by the impulses conveyed from these wounded parts.

I think that many of the phenomena of hysteria are phenomena of inhibition. Brain- or cord-centres are inhibited by an irritable ovary or uterus, or by some other source of irritation, or sometimes we have a lack of inhibition,—a want of control over ordinary functions,—and spasms and hyperæsthesia result. The shifting nature of hysteria is best explained in this way.

There is one point about the present case which I desire to call your attention to, namely, that there is no ovarian irritation, and that deep pressure produces in the ovarian region no disturbances whatever of the symptoms or patient. In many of Charcot's cases of grave hysteria, ovarian pain and tenderness have been marked features; and the professor lays great stress upon the occurrence of such symptoms, and upon the fact that firm ovarian pressure will, in hystero-epilepsy, arrest the paroxysms. Our experience does not coincide with this. In the case of hystero-epilepsy spoken of above, ovarian pressure did not arrest the fits; and this is our common experience.

In American women the ovaries do not seem to be often involved in hysteria, nor are we able to feel them or impress them by the methods described by Charcot. Often, too, I have seen very marked ovaralgia and ovarian tenderness without hysterical symptoms.

For the purposes of prognosis, it is important to decide whether, in such a case as this girl, there are organic changes in the peripheral nerves, spinal cord, or brain. Even when no organic change is present at the start in a hysterical woman, it may be brought about by the continued functional excitement of the nerve-centres. You are familiar with many affections which at first are functional and eventually become organic. I need only recall to

you cases of "tobacco-heart" and of heart-strain in soldiers: these conditions, resulting from abuse and overstrain, lead, finally, to hypertrophy and other organic diseases. Something similar may take place in such cases as the one before you: the motor centres and motor channels being constantly over-excited and over-taxed, permanent changes may be produced in the delicate nerve-tissue; sclerosis may result. The best test that I know of for determining whether a contracture has become fixed—the result of secondary organic change—in a case of hysteria is the effect of etherization. So long as, during anæsthesia, the members relax, there is reason for believing that no serious lesions have occurred. Now, etherization produces here complete muscular relaxation. Similar cases, of much longer duration, have recovered. The mere fact that the case has lasted so long does not prove the existence of organic lesion; and I am inclined to believe no such lesion exists, and that recovery is possible, and may be sudden. The case has had all ordinary therapeutics applied to it, without result so far.

I would like to discuss carefully the proper treatment, but my hour is expired, and I must leave this for a future lecture.

ORIGINAL COMMUNICATIONS.

WEAK SPINES IN YOUNG GIRLS, AND THEIR TREATMENT.

Read before the Philadelphia County Medical Society, December 15, 1880,

BY JOHN M. KEATING, M.D.,

Lecturer on Diseases of Children in the University of Pennsylvania, Visiting Accoucheur to the Philadelphia Hospital, etc.

MY intention this evening is to bring before you a subject that may at first sight appear a trivial one, but which more extended observation and careful study have led me to consider worthy of the attention of this Society.

Thousands of young children are at this time bending over their books in the crowded school-room, straining their eyes, narrowing their chests, and bowing the back upon whose erectness and resiliency they should in future depend not only for support, but for health,—even life. A few years hence, these very spines, now strained, weakened, and probably curved, will be called upon without further preparation to bear the brunt of the great requirements of society, and soon after to be tortured by the physical burden of maternity; or probably the store, the sewing-room, or the factory, aided by some inherited taint, will determine the lesion and give us the cases of phthisis, diseases of the heart, carcinoma, and the various chronic affections that fill our mortality tables.

I call particular attention, in my paper, to the girls, because they are by far the more important class, and the out-door games and occupations of the boys tend to obviate what the sedentary tasks of their sisters but tend to increase.

Once free from the thraldom of school, the boys break loose to unbend their backs and free their lungs; the girls, to saunter home, their arms burdened with books, to aid their mothers in domestic duties.

The infantile diseases of the spinal column, those that involve the structure, have received careful study, and now, thanks to Sayre, the body is at once placed in splints until the rickety diathesis is overcome by growth and a full supply of bony deposit. Even such cases of structural disease as develop later in life are now easily detected at their earliest manifestation, and either held in abeyance by immediate treatment or effectually checked in their course.

But it is my purpose to call attention to another class where spinal weakness, due to the strain of position,—a condition so insidious in its onset and masked in its course,—escapes attention till the frame, fully set by complete bony deposits, cramps the viscera, and, by impeding healthy action, forms a nidus for disease. The development of the skeleton is undoubtedly influenced by the activity of its muscles: symmetrically-developed muscles will produce straight bones. We read much of dystocia, we hear of pelvic distortions, of narrow diameters. Has any one endeavored to mitigate these evils by helping Nature to make normal what the requirements of dress and pursuit have tended from early life to deform? The remedy for those conditions that have suggested the forceps, the cranioclast, or "version by the feet" lies in the early development of the skeleton by proper physical training,—in other words, by educating the female child to be a mother, and if its diathesis be rickety train its pelvis as well as its brain. Far be it from me to

decry anything that will tend towards the most thorough education of the intellect: my object is simply to contend that study can be accomplished without cramped positions, and that weak spines are not essential to educated women. My attention has frequently been called in connection with dispensary and other practice to a series of cases that forms the basis of this paper. For better elucidation, and to avoid repetition, I shall group them under two heads,—the first comprising those young enough to go through the daily routine of school life and thereby suffer at once from its ill effects; the second, those who, after having spent years in developing their intellect at the expense of their muscular and nerve force, suddenly call upon them to bridge them over the most difficult period of their lives. The first group you recognize by their pale faces, bowed backs, and rounded shoulders, frontal and occipital headache, weak eyesight, cardiac palpitations, disordered digestion, and certain nervous combinations, chorea predominating. Stand at any school-room door on an afternoon in the early spring, and you will not fail to see the cases that fill our dispensaries. You read their remedy in their very faces,—a proper division of study and recreation, recreation that means not mere rest from book-work, but muscular exercise, good food, and fresh air.

To-night to the second group I wish to call special attention: a chapter devoted to its consideration might most appropriately bear for its heading the one prominent symptom, "backache." Free from the daily restraint of school life, their hours are devoted to the absorbing necessities of society, and their habits either become extremely active or extremely sedentary, the mania for violent exercise developing from the lassitude that follows nervous excitement; and from one extreme to the other will these girls drag out years of miserable existence whose monotony will be relieved only by the periodical tortures of dysmenorrhœa. That the functions are deranged is simply in accordance with the general physical strain. In all such cases the great muscles of the back are those most called upon, and soon, from excessive tension or want of nutrition, fail in their most important duty. The equilibrium which is maintained by the concerted action of those of either side is lost by the giving way of the muscles that malposition has tended to weaken, and the stronger group brought into play draw the spinal column where they will. Neuralgic pains, backache, and internal congestions are the result, to say nothing of the occasional permanent lesion in long-standing cases by the absorption of cartilage. Weariness from anæmia, chlorosis, and hysteria in all its forms is the inevitable sequence. Let me picture for you an example. A young girl comes to your office with the following history. Possessed of a naturally strong constitution and vigorous intellect, she has been ambitious, has graduated after years of close application and with the highest honors of her class. Her winters have been spent in the sedentary pursuits of the school-room; even her hours of leisure have been devoted to her books. Of course, the usual result—"break-down"—has followed, and the routine treatment of tonics has been adopted, and, so far as general appearance is concerned, the patient has been benefited by them. But the principal complaint is weariness, a continual feeling of fatigue, following the smallest amount of exercise, brought on equally well by standing and by sitting, by day and by night. This feeling of weariness is more decided in the back, and is so uncomfortable, not to say painful, as to require some constant form of pressure in the lumbar and sacral regions, which, when lying in bed, is brought about by placing a pillow in the hollow. There is also an aching in one of the shoulder-blades, and a feeling of weakness in the muscles at the back of the neck. Upon examination, your patient appears well nourished, but the muscles upon pressure are found to be soft and flabby. It will be noticed when the back is examined that the patient leans more or less to one side, and if allowed to assume a natural and (to her) comfortable position that the difference is often surprising. As a rule, the aching or weariness is found located in the muscles that form the convexity, because those on the concave or the side towards which the spinal column leans seem to draw it in that direction, and thereby stretch the muscular tissue of the opposite side. In several cases that I have seen, this view appeared to be strengthened by the fact that faradic contractility was slightly diminished on the outer convex or weaker side. I have seen cases where

the pressure seemed so great as to cause absolute pain from the curvature alone, and I have no doubt that, without any distinct disease as an initial lesion, a permanent tendinous contraction can take place after a time identical with that which requires surgical interference in other parts of the body. Certain it is that in one case that came under my notice the pressure caused all the symptoms of phthisis in the lung pressed upon, all of which were relieved by straightening the spinal column. It is scarcely necessary to enumerate further the complaints of a patient such as I have described if the condition has been one of long standing: the interference with circulation, the in-door life, the restlessness from nervous irritability, the reflex nervous disturbances, the loss of appetite and want of nutrition, will be shown by a tangled chain of evidence that will tax the power and patience of the most accomplished and amiable of diagnosticians. Various forms of uterine disease, with flexions, versions, and prolapses, ovarian engorgements, enlarged and displaced ovaries, will add to the confusion by their perplexing train of symptoms. Relaxation is the word expressive of the one general cause of such conditions, and in our treatment we must bear in mind the atonic condition of every muscle, nerve, and fibre of the whole body. The admirable teachings of Dr. S. Weir Mitchell have enabled us to value, above all things, absolute rest in all such and allied cases; and to insist that, in the majority of those to which I now allude, it is the primary factor in their treatment, is simply to add testimony which is not required to the great success that has attended its trial.

When examination shows us decided weakness in the muscles of the back, I have of late adopted a plan calculated to give the support which is needful until the nutrition and strength of the muscle have been increased by local treatment. Instead of the plaster dressing, which is so valuable at other times, I would suggest the use of some lighter material, cardboard, for example, which, softened by hot water, easily moulds, and when dry and hard forms a light and admirable splint. It may be applied in this way. A small strip, extending fully the breadth of the back from the lower border of the scapulæ to the most prominent portion of the sacrum, covered with linen, is applied, when softened, over a piece of canton flannel or some such material, while the patient is sitting, care having been taken that during the application the spinal column is erect. A few turns of a roller will secure it in place. I usually cut the cardboard heart-shaped, with the base upward and the apex down. When dry, the support will be found complete. The shoulders will rest on a level, the lower borders of the scapulæ firmly fixed upon the upper part of the board, this position being, I think, most important. The cardboard can be attached to the corset, taken on and off with it, and, as the clothing fits perfectly without giving the least hint as to what lies beneath, patients will wear it with comfort and willingly for any length of time. But above all things I believe in the daily use of the faradic current, applied to those muscles or groups that it is proposed to strengthen, and to them alone: thus, if the column leans towards the right side, faradize the muscles of the left. This, I believe, is of far greater value than we have been accustomed to consider it, for single muscles can thus be readily exercised to the exclusion of others, and exercise of this kind brings with it increased nutrition, strength, and development in size. With such a power, when applied with the perseverance it demands, what are we not capable of doing? The aurist will tell you of its use in increasing the muscular tonicity of the smallest and most delicate muscles of the inner ear. In diseases of the uterus so powerful is its local action, when properly applied on muscular fibre, as to make permanent a position in many cases which has needed for years the support of the pessary. I may almost predict for the oculist its value in restoring accommodation instead of the ever-fashionable glasses. It is the daily systematic use of a well-contracting current that is followed by the beneficial result, just as it is the mildest form of continued exercise, and not the spasmodic muscular effort, that makes a man powerful. Recommend your patient before retiring to hang by the hands from a horizontal pole for a few moments, to use cold sponging, friction, and, above all, when possible, massage, to exercise daily in the open air, which the back-support invites, as the want of it before discouraged. When strength is gradually accumulated, encourage that most healthy and invigorating exercise, swimming, which

is never followed by the ill effects so often seen in women from the overstraining of violent walking or horseback-riding.

THE SULPHATE OF HYOSCYAMINE AS A MYDRIATIC.

BY S. D. RISLEY, M.D.,

Lecturer on Ophthalmoscopy in the University of Pennsylvania, Ophthalmic and Aural Surgeon to the Episcopal Hospital at Philadelphia, etc.

UNTIL a comparatively recent date, ophthalmic surgeons were compelled to rely solely upon the sulphate of atropin both in the treatment of certain inflammations of the eye and for paralyzing temporarily the power of accommodation. Other agents have, however, been introduced, which rival the old mydriatic in their ability to set aside the power of adjustment and possess the added advantage of resigning their control more rapidly. My investigations with the sulphate of duboisine (*Amer. Jour. Med. Sci.*, April, 1880) and the hydrobromate of homatropine (ibid., January, 1881) have encouraged a similar investigation into the properties of hyoscyamine and daturine,—specimens of which, manufactured by Merck, have been kindly supplied me by Mr. George I. McKelway.

The present paper is a preliminary statement of the results thus far obtained from hyoscyamine.

In the following group of eight cases a solution of the sulphate of hyoscyamine, gr. ij to f℥j, was invariably used,—being first instilled in the clinic-room and a careful record made of its action over the pupil and accommodation.

In a few instances a solution, gr. j to f℥j, was furnished, to be used three times daily at home. At the succeeding visit the stronger solution, one or two drops in each eye, was again instilled, and the examination for the glasses made after a time varying from thirty minutes to an hour, or longer. In three cases the glasses were ordered after the single instillation, the power of accommodation being entirely set aside. In Case VI., two drops of the two-grain solution were applied very thoroughly. In twenty minutes she complained of giddiness, so that in crossing the room she walked as though suffering an attack of vertigo. Her glasses were ordered one hour and a quarter after the application, and she left the clinic-room without difficulty, the giddiness having nearly disappeared. In no instance was there any complaint made of dry throat or skin, nor was there the least conjunctival irritation following its use.

In Case VII. the lad's mother was disturbed in the night by his restlessness and talking in his sleep, which she thought must be due to the drops. He was using the one-grain solution at home.

In Case VIII. the result obtained under hyoscyamine was confirmed by the subsequent use of a four-grain solution of sulphate of atropine three times daily for two days.

Case I.—At 5 o'clock P.M. a minute quantity of a solution of the sulphate of hyoscyamine (gr. ij–f℥j) was applied to the conjunctiva of the lower eyelid without causing any irritation. In ten minutes there was some disturbance of near vision, and the pupil larger than in the other eye and slightly ovoid. In twenty minutes the pupil was dilated *ad maximum*, and J. 1 could not be seen. In thirty minutes J. 1 could be read only at the focus of a convex glass ($+\frac{1}{12}$ J. 1, 11″ to 13″; slight H.). At 12 o'clock the following day, nineteen hours after the application, which had not been repeated, the pupil was still widely dilated and immovable, and the paralysis of accommodation complete. At 5 P.M., twenty-four hours after the application, there was still complete mydriasis and no return of accommodation. At 9 o'clock A.M. the following day, forty hours from application, with $+\frac{1}{12}$ J. 1, p. p. $7\frac{1}{2}$″. At 3 P.M., $+\frac{1}{12}$ J. 1, p. p. $5\frac{1}{2}$″. On the morning of the fourth day, 9.30 A.M., the near point for each eye was the same (7″),—the normal range of accommodation.

Case II.—One drop of a two-grain solution of hyoscyamine was instilled into each eye of a girl 15 years of age. In ten minutes the pupil of O. S. was dilated *ad maximum* and fixed, that of O. D. retaining a slight resiliency. In twenty minutes both pupils were dilated *ad maximum* and fixed. In twenty-five minutes, with $+\frac{1}{6}$s J. 1, $11\frac{1}{2}$″–12″ for O. D., $10\frac{1}{2}$″–12″ for O. S.

On careful testing with trial-glasses, one hour after the instillation, she very positively selected O. D. $+\frac{1}{10}$s ⌒ $+\frac{1}{86}$c, axis 30°;
O. S. $+\frac{1}{9}$ s ⌒ $+\frac{1}{60}$c, axis 90°; and all accommodation was abolished. Seventy-two hours after the use of the drops, with the correcting-glass J. 2 could be read up to $6\frac{1}{2}$″ with O. D., 5″ with O. S. The pupils were dilated small-medium, and reacted quite promptly to changes of light and shade. Twenty-four hours later, the pupils were normal in size and action, and, with her correcting-glass, the accommodation had fully returned.

Case III.—In this case a small drop of two-grain solution was instilled in each eye of a patient of 43 years, suffering from retinal irritation, with spasm of accommodation simulating a considerable myopia. In an hour the mydriasis was complete and the accommodation was totally paralyzed, revealing hypermetropic astigmatism of $\frac{1}{48}$ in the highest meridian. The choice between several compound glasses could not, however, be made with certainty, the irritable condition of the eyes and the use of artificial light being the probable causes of the hesitation. A solution (gr. j–f℥j) was given to be used twice daily at home, and after sixty hours the paralysis was still complete. The two-grain solution was, however, again employed, repeated in an hour (this time two drops in each eye thoroughly applied), and the final choice of the glass was made without hesitation. Although the mydriatic was here freely used,—more freely at the last than duboisia could have been employed without liability to constitutional disturbance,—no unpleasant symptom was experienced beyond that incidental to the paralysis of the accommodation and the dilatation of the pupil.

Case IV.—A medical student, with marked retinal irritation and apparent myopia from accommodative spasm. Half an hour after the instillation of one drop of the two-grain solution the mydriasis was complete in the left eye, and $+\frac{1}{72}$c, axis 75°, brought the vision a little above normal. In the right eye an increment of accommodation remained, and one meridian seemed still myopic. After sixteen hours the instillation was repeated, and again twenty-four hours later. The myopic meridian of the right eye had now disappeared, giving place to simple hypermetropic astigmatism, no change having taken place in the left. With a convex glass added to the correction, J. 1 was read exactly at its focus, being blurred at every other point; *i.e.*, the paralysis was absolute. Thirty hours after the last use of the drops there was very slight return of the action of the iris, but the accommodation had returned sufficiently to allow medium print to be read, and with $+\frac{1}{12}$s J. 1 could be read up to 7″. Twenty-four hours later the pupils were still widely dilated and sluggish, but, with the correcting-glass, the accommodation had almost completely returned. Eighty hours after the last instillation the accommodation had been fully recovered, but the pupil was still dilated medium, though reacting promptly to changes of light and shade.

Case V.—Another medical student, with myopic eyes stirred up to spasm by the effort to wear too strong a glass. Fifteen minutes after the instillation of two drops of the two-grain solution in each eye the pupils were fully dilated and fixed, but the accommodation was not completely paralyzed, and had not become entirely quiet an hour after the instillation. On testing with the trial-glasses, one hour and a half after the instillation, the spasm was gone, the paralysis complete, and the compound correcting-glass was selected without hesitation. Twenty hours later the pupil was still fixed, but the accommodation had returned in part, and the spasm had recurred. Forty-eight hours after the use of the hyoscyamine the pupils were small-medium, and, with the astigmatism corrected, the accommodation but little below normal. When next seen, forty-eight hours later, the accommodation had completely returned, and the pupils were normal.

Case VI.—Mrs. H., æt. 49, suffering from asthenopia. A two-grain solution of the hyoscyamine salt was instilled, two drops in each eye, at 1.40 P.M. At 1.45 the right pupil was oval; left, no change. 1.47, both dilated medium and reacted sluggishly. 1.54, pupils dilated widely and were immovable, and vision had sunk from $\frac{20}{XXX}$ to $\frac{20}{C}$. At 2.20 she selected $+\frac{1}{42}$s ⊃ $+\frac{1}{60}$c, axis 90°, $V = \frac{20}{XX}$, for O. D.; $+\frac{1}{36}$s ⊃ $+\frac{1}{60}$c, axis 90°, $V = \frac{20}{XX}$, for O. S. Half an hour later, on careful measurement, the same glasses were again selected, and with them, and $+\frac{1}{12}$ added, she could read only at its focus, the paralysis of accommodation being complete. In twenty minutes after the application Mrs. H. complained of vertigo and walked across the floor with difficulty. In one hour and a half this had quite disappeared, so that she was able to return home without difficulty.

Case VII.—A boy of 10 years, with a family history of eye-trouble, suffering from the tax of his school-work. A convex glass had been ordered, in conformity with the ophthalmoscopic reading, but had failed to make him comfortable. Two drops of the two-grain solution were instilled in each eye, and in fifteen minutes the pupils were dilated *ad maximum* and fixed. In forty minutes all accommodation was apparently gone, but the full hypermetropia was not revealed except to the ophthalmoscope, and the astigmatism, though recognizable, could not be accurately measured. A solution (gr. j ad f℥j) was given, to be used three times daily for two days, and the two-grain solution was repeated on his return. The determination was now made with little difficulty, but a lingering doubt, caused probably by the irritability of the eyes, led to the continued use of the drops (one-grain solution). After twenty-four hours the determination was made without difficulty, and the accommodation was found absolutely paralyzed. When next seen, seventy-two hours after the last use of the drops, the pupils were still dilated to medium, but were prompt up to this point in their reaction, and the accommodation had in great measure returned. Twenty-four hours afterwards the pupils were about the same, and the

near point still a little outside of that first recorded.

Case VIII.—A student, 20 years of age, with hard-worked eyes, suffering extremely from straining to overcome a high hypermetropic astigmatism. The two-grain solution was instilled, and in twelve minutes the pupils were widely dilated; in twenty-five minutes they were dilated *ad maximum* and fixed. At the test, made within an hour after the instillation, the entire astigmatism was revealed, but $\frac{1}{48}$ of hypermetropia, shown by the ophthalmoscope, remained latent. A solution (gr. j ad f℥j) was given, to be used twice, at home, during the twenty-four hours, and was instilled for the third time forty-five minutes before the test. A satisfactory determination of the correcting-glass was now made, but to complete the case a solution of atropia (gr. iv ad f℥j) was substituted, to be employed three times daily. After forty-eight hours' use of the latter mydriatic, identically the same glass was selected for the right eye (the eye with which he was accustomed to work, the other being more defective), while for the left a nearly equivalent glass, with a slight change in the relation of spherical and cylinder, was preferred. The vision was slightly better in both eyes, as under the mydriatics they had lost much of their irritability. In this case at the first application only was the two-grain solution employed, and the one-grain solution only three times in the twenty-four hours.

The left eye, selected after hyosc. gr. ij sol., one hour, $+\frac{1}{36}$s ⊃ $+\frac{1}{18}$c, axis 85°.

The left eye, selected after hyosc. gr. j sol., twenty-four hours, $+\frac{1}{18}$s ⊃ $+\frac{1}{16}$c, axis 90°.

The left eye, selected after atrop. gr. iv sol., forty-eight hours, $+\frac{1}{20}$s ⊃ $+\frac{1}{14}$c, axis 85°.

No.	Age.	Length of Use.	Return of Accommodation.	Formula of Correction.	Remarks.
1	...	1 hour (single application)	90 hours	...O. D. $+\frac{1}{48}$s	Pupil still slightly dilated at 90 hours.
2	15	1 hour (single application)	96 "	O. D. $+\frac{1}{16}$s ◯ $+\frac{1}{36}$c, axis 30°.. O. S. $+\frac{1}{8}$s $+\frac{1}{60}$c, axis 91°..	Pupils normal at 96 hours.
3	43	...68 hours	...100 "	O. D. $+\frac{1}{60}$s $+\frac{1}{72}$c, axis 30°.. O. S. $+\frac{1}{48}$s ◯ $+\frac{1}{72}$c, axis 120°..	Pupils dilated medium, but prompt.
4	21	...40 "	... 77 "	O. D. $+\frac{1}{72}$c, axis 165° O. S. $+\frac{1}{72}$c, axis 75°	Pupils dilated medium, but prompt.
5	20	1½ hours (single application)	Nearly complete; 48 hours	O. D. $-\frac{1}{18}$s ◯ $-\frac{1}{60}$c, axis 120°.. O. S. $-\frac{1}{18}$s $-\frac{1}{60}$c, axis 75°..	Pupils dilated medium, but prompt.
6	49	1¼ hours (single application)	100 hours	O. D. $+\frac{1}{42}$s $+\frac{1}{60}$c, axis 90°.. O. S. $+\frac{1}{36}$s $+\frac{1}{60}$c, axis 90°..	Giddy. Pupils dilated medium, but prompt.
7	10	...72 hours	Not quite complete; 96 hours	O. D. $+\frac{1}{36}$s $+\frac{1}{72}$c, axis 75°.. O. S. $+\frac{1}{36}$s $+\frac{1}{72}$c, axis 105°..	Pupils dilated medium, but prompt.
8	20	...25 "	...	O. D. $+\frac{1}{24}$s $+\frac{1}{14}$c, axis 105°.. O. S. $+\frac{1}{20}$s ◯ $+\frac{1}{14}$c, axis 85°..	Confirmed after atropia, 48 hours.

It will be seen from the foregoing that the hyoscyamine is a powerful mydriatic; that in the rapidity of its action over the iris and ciliary muscle, and in the duration of its control, it is more like duboisine than like atropine. The giddiness, which, however, occurred in but one instance, was also more like the constitutional effect of duboisine; but it was not attended by the sense of weakness in the lower extremities produced by that drug when used incautiously. That there is little danger of annoyance from the constitutional impression, when used in solution no stronger than two grains to f℥j, is indicated by the fact that, though used profusely in several of these cases, there was no disturbance whatever except in the case of Mrs. H., above noted, where the giddiness was possibly due to the rapid paralysis of the accommodation and consequent blurring of vision. Regarding the effectiveness of hyoscyamine in paralyzing the accommodation, further observation will be necessary; but Case VIII. is important in this connection, since the subsequent prolonged use of atropiæ sulphas only served to confirm the result obtained under the hyoscyamine.

In closing this preliminary statement, I desire to express my obligations to Dr. B. Alexander Randall and Dr. James Wallace for their efficient aid in making and recording these observations.

1430 WALNUT STREET.

HOMATROPINE HYDROBROMATE: IS IT A POWERFUL MYDRIATIC?

BY WILLIAM F. LITTLE, A.M., M.D.,

Chief of the Eye Clinic, Jefferson Medical College Hospital.

MY attention was first called to homatropine hydrobromate by a short notice in the *American Journal of the Medical Sciences* for July, 1880. At the annual meeting of the American Ophthalmological Society, held in July, I spoke to several

members individually about it, and no one had any knowledge of it. I was unable to obtain possession of the drug until some two months ago.

Dr. Schell, in Nos. 336 and 337 of the *Philadelphia Medical Times*, Dr. Keyser, in No. 338 of the same journal, and Dr. Risley, in the January, 1881, number of the *American Journal of the Medical Sciences*, have brought the drug before the profession in this country, and many have had opportunity to test its value. Can we claim for it all that is desired as a mydriatic for the purpose of full refraction? It has been used sufficiently in my dispensary service at the Jefferson Medical College Hospital and in my private practice to enable me to express an opinion as to its capabilities and position among the mydriatics available for refractive purposes. My private students—several physicians and professional men—were my first cases; several had been refracted under atropia or duboisia previously, and one, under my own observation, had, after a sufficiently prolonged interval, a solution of atropia, gr. iv, duboisia, gr. iv, and homatropine, gr. viii.

Dr. Schell advocates a solution xvi gr. Dr. Risley says a ii gr., iv gr., or vi gr. is sufficient. I selected a solution viii gr. to the ounce without bringing any data to bear; more than fifty eyes have been examined by me. I merely wish to explain briefly what I have found it worth. In procuring refraction, a mydriatic is required that will paralyze the ciliary muscle, or if it is not accomplished we should be cognizant of it. I am an advocate of refraction as positive as it can be made, and, having experienced the advantages of a full correction and the permanence of it where spasm of accommodation or choroido-retinal irritation is overcome, we should seek this in the treatment of our cases.

The use of homatropine in my dispensary service has been given up for the following reasons. Its short duration prevents a second trial, and, it being required to be used a second time, a variableness is found in the results of myself and associates that leads to uncertainty, remembering that a patient with your glass on has you by the nose, so to speak, and can lead you into pleasant or unpleasant relations with himself and others. As much certainty can be attained by the ophthalmoscope or the ameliometer of Prof. Thomson—no spasm of accommodation existing, methods being available to recognize this point—as is obtained by the use of homatropine. The observer must have control of his own accommodation to do this, however. By this statement I mean that I feel as certain of my work with the ophthalmoscope as I do with homatropine; and how closely an ophthalmoscopic examination reveals defects is fully appreciated by all observers, few being able to command control of their own accommodation, as is required to make the result effective. Preference, then, should be given to a drug that gives more time, more certainty, and full corroboration by the ophthalmoscope in dispensary service.

The same holds in one's consulting-room, and when the ophthalmoscope, with other methods, cannot give a diagnosis, there should be no uncertainty in the drug used.

Patients complain very little as to the length of duration of the annoyance of mydriatics between duboisia and homatropine where symptoms occur that they are only too glad to be relieved from, even under the delay that occurs in strong solution of atropia.

Advocates of homatropine, when employing atropia, not unfrequently employ the drug (atropia) for several days prior to their making an examination, presuming that all cases have spasm of accommodation or choroido-retinal irritation; yet they use a drug which is more evanescent and has some uncertainties after one instillation in the same class of cases.

Dr. Risley says, "In other cases, on subsequent examination under atropia or duboisia, slight changes were made in the glasses at first chosen under homatropine, but not greater than are often made after the continued use of atropia or duboisia. It also happened that when the first examination was for any reason not satisfactory, and where the homatropine was continued, a second examination revealed a slightly higher degree of hypermetropia or astigmatism. More frequently, however, only a greater certainty in placing the direction of the cylinder axis was observed, or an improved sharpness of sight with the same glass at first selected, due, no doubt, to the subsidence of the choroido-retinal irritation." It is "the slight change in the glass," or "slightly higher degree of hypermetropia or astigmatism," or "greater certainty in placing the direction of the cylinder axis was observed," or "an improved sharpness

of sight,"—it is all these that are so apt to be found under homatropine that enables its uncertainty to be almost assured, and these slight uncertainties make the result less valuable; and when this can be attained by the ophthalmoscope, the observer controlling his own accommodation, how can homatropine compare with either atropia or duboisia where prolonged use is required, where spasm of accommodation occurs?

Homatropine hydrobromate, so far, seems to stand in the position of hydrobromic ether. Prof. Thomson, of Philadelphia, and Prof. Noyes, of New York City, have given expression to me very much in the same vein as to the capabilities of the drug.

I find it of service in elderly persons with hypermetropia, whose accommodation has failed, using it where atropia might produce a glaucomatous condition, and I have feared with them duboisia might have the same effect as atropia occasionally has, but as yet no cases with either duboisia or homatropine have been quoted. For mere mydriasis to examine the fundus of the eye and other internal tissues it is most serviceable. Its therapeutic effect has not been attempted.

A further acquaintance with the drug and methods of using it may make it more available, but, so far, atropia and duboisia are the more efficient in correcting optical defects.

219 South Seventeenth Street.

COMPOUND COMMINUTED COMPLICATED FRACTURE OF JAW.

BY HENRY M. WETHERILL, M.D.

JOHN G., æt. 32, single, was admitted to the Surgical Ward of the Pennsylvania Hospital, under care of Dr. William Hunt, June 21, 1880.

This man had his face crushed in a machine-shop, between the floor and a roller. Upon admission, the right side of his face was drawn very much inward, the features twisted over towards the opposite side, and the mouth puckered up as though the patient was whistling. On the right side of his face was a lacerated wound two and one-half inches in length, commencing at a point half an inch below and immediately under the angle of the mouth, and extending downward and backward, crossing the jaw. The lower jaw was very obliquely fractured and very badly comminuted at a point corresponding to this wound. The articulating end of the right side was luxated forward from its glenoid cavity, and the lower end of the upper fragment was carried over to the opposite side of the mouth, this sharp point piercing the left cheek.

The hemorrhage was very free, the floor of the mouth and the mental artery having been lacerated. The neighboring soft parts were much contused.

The luxation was easily reduced, but it was found to be impossible to approximate the main fragments until all of the comminuted bone was removed, with three of the teeth, the latter carrying with them portions of the alveolar border of the jaw. Four spouting vessels were then ligated, and the oozing controlled by very warm water. The long, sharp, oblique upper fragment was next forced down into position, when it was seen that the loss of bone was very considerable, a triangular cavity or hiatus being thus formed, the base corresponding to the base of the jaw, the apex to the alveolar border. So strong was the action of the temporal, pterygoid, masseter, and buccinator muscles as to require considerable effort to hold the upper fragment in position.

It having been found impossible to retain the fragments in apposition by any of the ordinary appliances, the patient was etherized, and the writer, by the kind permission of Dr. Hunt, operated. The existing wound was enlarged by carrying a knife up through the angle of the mouth, and a broad flap was dissected back over the extremity of either fragment, thus fully exposing the sound bone.

The periosteum was found to have been very much torn. Several bleeding vessels were ligated, and either fragment near its extremity was drilled through in two places and the fragments brought into approximate apposition by the passage of very stout silver wires through the drill-holes, the ends of each pair being twisted firmly up, left long, and carried outside the external wound. The soft parts were brought together by pins and twisted sutures. Dressing,—carbolized lint, a pasteboard jaw-cap, and Barton's bandage. This arrangement held the very irregular fragments without motion, and the dental line was almost perfect. Ordered liquid diet.

Upon the 30th the sutures in the soft parts were all removed, the pins having been withdrawn five days previous. The ligatures were all away, and the condition of the patient good. The dental line was well preserved, and the fragments were firm.

At no time was there any marked rise of temperature, and the man fed well on

fluids. From time to time various shells of necrosed bone came away, but progress towards recovery was steady.

Under date of August 21 is noted "that the last bone suture came away, and careful manipulation reveals that the union is perfect, the contour of the jaw good, and the line of the teeth well preserved. He masticates solid food as well as before the injury, and the only resulting deformity is the slight one of a cicatrix running downward from the angle of the mouth to the base of the jaw."

SOME TABULAR RESULTS OF THE MOVEMENT-CURE.

Presented to the Philadelphia County Medical Society at the Meeting of November 24, 1880,

BY BENJAMIN LEE, A.M., M.D.

MANY members of this Society will remember having seen in Machinery Hall, at the Centennial Exhibition, a very interesting exhibit of apparatus intended for administering the Swedish movements. The table which follows is an abstract from the report to the National Board of Health, at Stockholm, of the Medico-Mechanical Institute of Gothenburg, Sweden, in which similar apparatus is in use. It covers a period of five years, from 1867 to 1872:

Diseases.	Number of cases.	Cured.	Benefited.	Not benefited.
Diseases of the heart, functional	10	9	...	1
" " " organic	49	...	42	7
Rush of blood to the head	28	10	16	2
Recurring hemorrhage from nose	2	2	...	...
Defective capillary circulation	7	7	...	...

Total	717	204	436	77

One of the most important and successful institutions for carrying on this mode of treatment outside of Sweden is that of which Professor Axel Sigfrid Ulrich, M.D., is director, in the city of Bremen. Professor Ulrich is a man of acknowledged ability, as witnessed by the honors which he has received, being a Knight of the Swedish Order of Wasa, Member of the Medical Society of Stockholm, and corresponding member of the Royal Society of Medicine and the Natural Sciences of Brussels, of the Medico-Chirurgical Academy of Barcelona, of the medical societies of Paris, Antwerp, Athens, etc.

I append a summary of the twenty-third annual report of his institution for the year ending July 1, 1879:

Diseases.	Received.	Cured.	Greatly improved.	Improved.	Unimproved.	Irregular in attendance.	Still under treatment.
Anomalies of innervation, —disturbances of nervous activity (chorea, etc.)	2	...	...	2	...	...	...

During the same period the following cases were successfully treated by massage alone: sprained ankle, 6; sprained knee, 2; sprained wrist, 4; sprained fingers, 3; tendo-vaginitis of foot, 2; chronic synovitis, 2. The average number of sittings in the cases of sprain was between five and six. This, I am aware, will scarcely seem credible to those who are accustomed to put a sprained ankle or wrist into splints, starch, or plaster, and see it drag along for weary months before it again becomes a useful member. With the immediate, persistent, and frequent use of this means, however, few sprains will disable the suf-

ferer for more than three or four days, and many will be entirely relieved at a single sitting if it follows the accident within an hour or two.

NOTE ON THE HYGIENIC INFLUENCE WHICH MAY BE EXERTED BY HOUSE-PLANTS UPON INDIVIDUALS WHO ARE PREDISPOSED TO PHTHISIS PULMONALIS.

BY ELY McCLELLAN, M.D., U.S.A.

FOR the past three years there has been almost constantly under my observation a case which seems to be thoroughly corroborative of the views advanced by Dr. I. M. Anders in his paper "On the Hygienic and Therapeutic Relations of House-Plants."*

E. M. is a gentleman 30 years old, who belongs to a family in which there is a marked history of phthisis pulmonalis. His physical appearance would indicate that he might be subject to the disease, but he has, as yet, escaped its development.

The history of this case involves the families of both the father and mother. The father, although born of tubercular parents, escaped the disease, but the mother died at comparatively an early age, leaving a family of five children, four of whom have died of consumption. Of these children three died between twenty and twenty-five years of age; one died in his thirty-ninth year, after a long illness, the last two years of which were under my observation.

E. M. is the youngest of the family. His life, with the exception of the last eighteen months, has been devoted exclusively to sedentary pursuits. At twenty-three he married, and, as he was then engaged in an occupation which required his residence at an isolated locality, for both amusement and occupation his wife commenced the cultivation of house-plants. She soon became an enthusiast, and a profusion of plants, especially those of the foliage varieties, accumulated in her house. As they resided in an extremely changeable climate, where during the cold months constant watchfulness is necessary for the preservation of plants, her bedroom and the adjoining sitting-room were arranged for that purpose.

Before his marriage E. M. complained of, as he expressed it, "a weakness of the chest, and a constant liability to take cold." Since his marriage, with the exception of an occasional dyspeptic ailment, he has seemed a healthy man; and it is but reasonable to attribute his escape from the disease which has destroyed so many of his family to the fact that he lives, and has lived for the past seven years, in apartments well stocked with thrifty plants.

December, 1880.

TRANSLATIONS.

DISEASES OF THE KIDNEYS DEPENDENT UPON SYPHILIS.—Dr. E. Wagner (*Deutsches Archiv für Klinische Medicin*, 28ten Bd., p. 94) says that although kidney disease as a result of syphilis is unusual, yet it is not as rare as has been supposed. In 9000 autopsies Wagner found 63 cases of kidney trouble. Of these 8 were acute Bright's disease, 4 chronic, 7 granulated kidney, 6 atrophy of one kidney, 35 amyloid degeneration, and 3 syphiloma. Speiss, in 220 autopsies of syphilitic cases, found pathological changes in 147. Only 7 had gummatous interstitial nephritis. Of 10 cases of congenital syphilis with diseased kidneys there were 3 each of parenchymatous nephritis, amyloid nephritis, and infarction, with 1 of simple interstitial nephritis. Bamberger found 49 cases of syphilitic disease in 2340 cases of acute and chronic Bright's disease. A. Beer describes very fully the various anatomical conditions in the kidneys of syphilitic persons. 1. Small circumscribed nodular formations (gummatous tumors) in otherwise normal or differently-diseased kidneys. 2. Simple interstitial hyperplasia, mostly irregular with the formation of cicatrices; rarely scars in otherwise normal tissue. 3. Diffuse cellular hyperplasia of the interstitial tissues, mostly with lardaceous degeneration of the vessels and manifold atrophies of the new formation, as well as with peculiar parenchymatous changes. These were particularly small fatty deposits; rarely this form without lardaceous degeneration. 4. Purely parenchymatous affections. Without other aids to diagnosis, only the first and third of these forms can, according to Beer, be regarded as characteristically syphilitic.

In Wagner's study of these diseases he divides his cases into several categories. 1. Under the head of acute Bright's disease he gives the histories of three cases where this affection was either observed in patients under the full influence of the early stages of syphilis, or where the symptoms disappeared under the use of antisyphilitic remedies, and follows these with five more cases where post-mortem examination of patients who had showed symptoms of syphilis during life revealed parenchymatous nephritis with hemorrhage, etc. 2. Under the head of subacute or chronic Bright's disease Wagner gives four cases similar to those in the first division, except that the autopsy showed in each case the second stage of Bright's disease. 3. Under the head of granular kidney seven cases are included, in four of which a microscopic examination was made. General characteristic appearances were not noted; in particular there was no constant arterial affection. The coincidence of the syphilitic symptoms and the kidney disease appears to have been made out in each case.

Under the head of unilateral atrophy of the kidney six cases of constitutional syphilis are given where marked contraction of one kidney was found with compensatory hypertrophy of the other, which was either normal or showed amyloid degeneration. While other causes might have been adduced for the atrophy in these cases, syphilis was the most likely. Weigert observed the same condition in two instances, and found arteriitis obliterans as first described by Heubner in syphilis. Macroscopically the kidneys were quite smooth; microscopically the changes were closely similar,—extreme disturbance of the cortical canaliculi, sometimes with entire, sometimes with contracted glomeruli in a stroma diffusely infiltrated with small cells.

Wagner observed thirty-five cases of amyloid degeneration of the kidney, and gives brief notes of the most interesting. Tuberculosis and also amyloid degeneration of liver and spleen were present in many of these cases. Some cases were cured. Finally, Wagner gives several cases of syphiloma, one of which had apparently been cured by treatment. He adds to this a number of references. The article is a very valuable one, and is carefully worked up.

A Case of Intermittent Articular Swelling.—Dr. Kolbe's case (*Deutsche Med. Wochens.*, January 22, 1881) was that of an unmarried lady of 32, of a neuropathic family, who had never suffered from any serious disease, but showed signs of general impoverishment of the blood. Seven years previously she had stumbled in ascending a staircase, and had immediately experienced a shooting pain in the left knee. Nevertheless, the patient danced frequently the ensuing evening. On the next day a well-marked swelling of the knee-joint was observed, which necessitated the application of a plaster-of-Paris bandage. When this was removed, the swelling was found to have disappeared; but it reappeared within two or three days. This recurrence was observed, in spite of repeated bandaging, for more than six months, after which the knee returned to its normal condition, except that it was weak.

Two years later the patient again injured this knee, and although the swelling, etc., were reduced by treatment, regular remissions at intervals of nine days began to be observed. After the use of an acid ferruginous mineral water the intermissions grew longer and the relapses more and more irregular. But again, a year or so later, after a fresh fall, the knee trouble began once more, and this time (summer of 1878) the patient called in Dr. Kolbe. She complained of weakness in the left leg, with occasional pain in the left knee-joint. Her gait was normal, but she became easily tired. The alar ligaments were slightly swollen and doughy. After using bog-baths for some weeks, the patient appeared nearly well.

The following summer, however, the disease again recurred, following some slight over-exertion. Hydropathic and other treatment improved the condition of the joint, but the disease a few months later took once more a distinctly periodical course. Every eleventh day the patient, without having experienced any prodromal signs, observed on waking that her left knee was decidedly swollen. The swelling increased without pain until the evening of the twelfth day, and gradually disappeared on the thirteenth and fourteenth days. The only disturbance was that of difficulty of locomotion. The disease kept on in this intermittent course for nearly a year, the patient becoming meanwhile greatly depressed and anæmic from moral causes. Examination showed each remission to be followed by serous effusion.

Fifteen grains of salicylic acid, given every two hours during two days before the expected attack, prevented its appearance. As this disturbed the stomach, Fowler's solution, with a fixed silicate bandage to the knee, was prescribed, and the patient confined to a wheel-chair. By this means a perfect cure was attained.

Secondary Syphilitic Laryngitis.—Dr. Gougenheim, in a lecture recently reviewed in *La France Médicale*, says that this affection is not of infrequent occurrence, being found in two-fifths of all syphilitic cases. It has never been carefully studied until lately with the aid of the laryngoscope. The parts of the larynx affected are swollen: when the syphilis is advanced, the tumefaction may become general. It is thus a grave form of the disease, intermediate between secondary and tertiary syphilitic laryngitis. Ulcerations are frequent, usually seated upon the epiglottis, particularly on its free border. They are somewhat large and of an irregular shape. Occasionally they are deeply excavated. The swollen parts may remain a long time in that condition; sometimes even the tissues become indurated and degenerate in a definitive fashion. The duration of the affection is from two weeks to two months; sometimes, however, relapses are frequent. The diagnosis, which presents no difficulty, is based on the occurrence of the ulcerations and on the coexistence of other signs of syphilis. The prognosis is favorable; the treatment is general and local. The latter consists in the application of ten to twenty per cent. solutions of nitrate of silver.

Carbolic Acid Applications in Erysipelas.—Subcutaneous injections have already been employed, and not without success, about the borders of the parts involved in cases of erysipelas. In private practice this method cannot be employed, at least in erysipelas of the face. The following formula, which has been employed for some years by Dr. Rothe, of Altenburg, seems, if not to arrest the course of erysipelas, at least to abridge considerably its duration and to lessen its gravity. Dr. Rothe bathes the affected surfaces with the following liniment:

℞ Acidi carbolici, gr. xv;
Alcoholis, ♏xv;
Ess. terebinth., ℥ss;
Tinct. iodini, ♏xv;
Glycerinæ, ℈iv.—M.

These applications are quite neutral; they do not even cause heat of skin. From the next day it is pale. This plan does not, any more than previous methods of local treatment, prevent the extension of the disease elsewhere, but in bathing the affected surfaces a rapid retrocession is obtained, so that erysipelas of the face lasts only three or four days. The places bathed every two hours are covered with a thin layer of cotton kept in place by a bandage. The various internal symptoms are to be combated with the usual remedies.

Fracture of the Palatine Arch.—Dr. Apicella (*Le Réveil Méd.*, 1881, p. 290; from an Italian source) gives the case of a man who was kicked by a horse on the right jaw. Epistaxis followed. The soft parts were bruised without solution of continuity in the skin; there was abnormal mobility of the right half of the palatine arch and the superior maxilla, which last was entirely displaced. Intense pain was caused by any attempt at palpation; the teeth on this side were loose. The diagnosis of longitudinal fracture of the hard palate was made. The treatment consisted at first of bladders of ice externally, and soft food. Three days later, the tenderness of the parts was much decreased, and the fragments could be replaced. This having been done, wire ligatures were run through between the teeth of the fractured and those of the neighboring sound parts of the maxilla. A bit of cork was then shaped to fit the two dental arches, and was applied between the two maxillæ, being retained firmly in place by a bandage. Cold applications were continued, with liquid food, and the patient was forbidden to talk or to masticate. On account of his indocility it was necessary to re-apply the wires at this stage; but at the end of twenty days union was complete.

Reflex Urinary Paralysis.—At a recent meeting of the Société de Chirurgie (*Le Progrès Méd.*, 1881, p. 29) M. Marc Sée read a report respecting a man who, after a blennorrhagia of six or seven weeks' duration, was suddenly seized with difficulty of urination. After exploration and catheterism, the physician, Dr. Dieu, diagnosticated a rapid stricture. Catheterism became more and more difficult, and internal urethrotomy was decided upon. The impossibility of introducing a director caused the operation to be postponed.

Meanwhile, the lower limbs lost power rapidly. Catheterism having been once more attempted, M. Dieu at last perceived certain rugosities which led him to suspect the presence of a urethral calculus situated behind a stricture and acting as the cause of a reflex paralysis. After various ineffectual attempts to push the calculus back into the bladder, external urethrotomy was practised upon a conductor, resulting in the removal of a calculus one centimetre long by three millimetres in diameter. The paraplegia—which, it is proper to say, had already begun to improve—rapidly disappeared after the operation.

Action of Salicylated Camphor.—Dr. Lajoux, in searching for a surgical dressing which would fulfil the double object of acting on the albuminoid ferments and on the inferior organisms, found that salicylic acid would fulfil the first of these indications and camphor the second. He therefore conceived the idea of combining the two, and has produced a compound to which he has given the name of salicylated camphor. Dr. Henrot (*La Presse Méd.*, 1881, p. 25; from *Union Méd. et Sci. du Nord-Est*) has studied the therapeutic properties of this compound with decidedly satisfactory results. In a case of ulcerative lupus occurring in a syphilitic patient, where the sores had resisted internal treatment and had not been affected by the local remedies used, a pomade of salicylated camphor caused the ulcers to put on an improved appearance within one or two days, the patient being entirely cured in a little more than a month. In the case of a phagedænic ulcer of the fourchette in a young woman, lasting six months and destroying a large quantity of tissue, a cure was effected by this remedy in a fortnight. Dr. Henrot suggests its employment in superficial epitheliomata and in indolent leg-ulcers.

Nitrite of Amyl in Cystitis.—Weisser (*Med.-Chir. Centralbl.; Le Réveil Méd.*, 1880, p. 259) calls attention to the antiseptic properties of nitrite of amyl. He presented before a German medical society a bottle containing urine which had been preserved without alteration for three years, the cork only having been moistened with nitrite of amyl. Weisser has also proved the effective action of nitrite of amyl in cystitis. A man of sixty had suffered for five years with chronic catarrh of the bladder. Injections of twenty centilitres (6½ oz.) of a solution containing three drops of nitrite of amyl were made twice daily with the aid of a Nélaton's catheter. Antispasmodics were administered meanwhile to relieve the tenesmus. At the end of six weeks the patient was entirely cured.

Scrofula and Tuberculosis.—In the course of a discussion had on this subject recently in the Société Médicale des Hôpitaux (*Bull. Gén. de Thérap.*, 1881, p. 34) M. Rendu concluded his remarks with the following statement:

1. The so-called tuberculosis nodule is not a specific element; it is found in a number of accidental neoplasmata.

2. Scrofula is a true diathesis, characterized by a series of variable manifestations upon which it impresses a special physiognomy.

3. Tuberculosis, on the contrary, is not a diathesis; it presents itself with the aspect of the parasitic diseases, always ready to germinate when the organism becomes debilitated.

4. The relations of scrofula and tuberculosis are nothing more than those of seed and soil: scrofula is the soil, tuberculosis the parasitic germ.

Hypodermic Injection of Metallic Mercury in Syphilis.—Dr. Luton uses this method with success. He shakes one to two globules of mercury with sixteen minims of glycerin in a bottle, and injects under the skin. By amalgamating certain metals with the mercury, these also may be introduced hypodermically.

Parasite in Lepra.—MM. Hillairet and Gaucher have communicated to the Société de Biologie the result of their preliminary experiments instituted for the purpose of ascertaining whether or not a parasite exists in the blood of leprous patients.

After taking precautions to prevent the introduction of foreign fungi, these investigators found the bacteria of leprosy multiply and develop under their observation, giving rise to chains of articulated micrococci, and to simple and ramifying filaments, presenting the ordinary appearance of the fungoid lower organisms.—*Le Progrès Méd.*, 1880, p. 1039.

Snow-Blindness, according to Dr. Reed, of Detroit, can be cured by the administration of nitrite of ethyl.—*Canadian Journal of Medical Science.*

EDITORIAL.

PROFESSIONAL SECRETS AND THE LAW.

WE desire to call especial attention to a letter from Dr. Sturgis, of New York, in another column of this issue, because it very ably assaults the position assumed by this journal on a very important subject. There is no more delicate situation in which a physician can be placed than that of the case detailed by Dr. Sturgis. Yet we think the case is not altogether to the point, or, at least, does not afford an objection to a properly-worded law. The immediate context of the paragraph quoted from the code of 1876 is not known to us, but, certainly, in a rightly-constructed code either the paragraph itself or its context should show that the witness-box of a court of justice is referred to, and not the necessary relations of daily life.

Further, we doubt very much whether even the New York law would be influential in preventing revelations in such a case as the one mentioned. Most physicians practising in a State where there were no legal restrictions would hesitate very seriously about making any revelations concerning their syphilitic patients even to a *fiancée*. If they did make such revelations, the law of slander would at least stand *in terrorem* over them, and the fear of it, with the sense of betrayal of trust which must come to a physician so acting even to save an innocent woman, would lead to the disclosures being made in an indirect rather than a direct manner; and we fail to see why this could not be done in either instance. It is, of course, highly improbable that a man would actually commence a libel suit against the physician; the necessary self-exposure and ruin of character would deter; but this would deter just as much from a prosecution under the New York statute. Again, very probably a judge would decide the disclosure "a privileged communication," and therefore, if true, harmless to the man making it. Public opinion would be too strongly in favor of the doctor for him to be sacrificed, but certainly some loophole also would be found in New York, for it is a gross libel to say that—at least in American courts—justice is blind; or, perhaps, if justice be blind, lawyers and judges are so lynx-eyed that they can always find escape when they wish to and when public opinion demands it.

Of course, occasions would arise in which the law would work hardship, or, possibly, injustice; but we still maintain that these cases must be few, and that their rare occurrence is less painful, less deleterious to the general medical profession and to the individual physician, than the present code, which attempts to make the doctor a legal spy upon those who come to him, and requires him, on penalty of hard labor and the striped jacket of a convict, to act as a detective for the Attorney-General, and report every case of abortion, etc., which comes to his knowledge.

The objections urged by Dr. Sturgis can, it seems to us, be overcome by the alteration of a single word in the law, and we earnestly call the attention of the committee of the State Society to this: let the word "compelled" be substituted for "allowed," and all proper protection and latitude are given to the conscientious physician. The paragraph would then read:

"A person duly authorized to practise physic or surgery shall not be compelled to disclose any information," etc.

PERFUMED CARBOLIC ACID.
Carbolic acid, ℈i;

Alcohol, ʒiv.

THE LIBRARY OF THE COLLEGE OF PHYSICIANS.

EVERY lover of medical culture must be well pleased by the growing interest in medical libraries in this country. Both Boston and New York seem to be stirred up in this matter, and, indeed, under the energetic efforts of Dr. Chadwick, in the former city almost a *furore* has been created.

We are delighted, however, to know that our own city still leads. There are now in the library of the College of Physicians nearly twenty-five thousand volumes, of which six thousand are in the Lewis Library. We believe that all the books are in excellent condition, and, after much delay and some abortive attempts, a card authors' catalogue is being rapidly and carefully prepared. It is to meet the expenses of this catalogue that the annual dues of the College have been raised to fifteen dollars; and, the members once accustomed to such payment, there will no doubt be a considerable annual surplus for the purchase of books when the money is no longer needed for cataloguing.

We trust that no attempt at a subject catalogue will be made. Dr. Billings has rendered this an absolute waste of time and money. If the latter article should prove to be embarrassingly plenty at the College, a little of it might well go to help the Index Medicus, which can always be employed as a continuous subject catalogue by ticking with ink such references in it as are in the College library.

CORRESPONDENCE.

February 12, 1881.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—From an item in the *New York Medical Record* I note that the medical profession of Pennsylvania, with the encouragement of the *Philadelphia Medical Times*, is trying to secure the passage of an act not only to render knowledge acquired by a physician during professional attendance a privileged communication, but also to prevent a physician from using such knowledge in any way, shape, or manner.

The argument made in support of such a law is that such a one has lasted for some time in New York State with satisfactory results. Such, however, is not the case. In the last published report of the Transactions of the State Society of New York (1880), the president, Dr. Didama, of Syracuse, in his inaugural address, makes the following remarks, which, as they are so pertinent to the matter in hand, I shall quote in full:

"Some modification seems desirable of the statute forbidding physicians from divulging any information acquired at the bedside of the patient.

"The code of 1876, section 834, reads, 'A person duly authorized to practise physic or surgery shall not be allowed to disclose any information which he acquired in attending a patient in a professional capacity, and which was necessary to enable him to act in that capacity.'

"On the face of it this statute seems to shut the mouth of the educated physician trained to habits of reticence, while it leaves unrestrained the babbling tongue of every unprincipled quack who happens to hold a bogus or forged diploma, and who is, consequently, not 'duly authorized.'

"The courts hold not only that a physician is forbidden to divulge any knowledge affecting the character or reputation of his patient, but that he shall not be permitted to testify to any information which he may have received from the sick person regarding any disease whatever. Gross injustice may result, and probably has resulted, from the enforcement of this law. In one instance within the knowledge of the speaker, where a patient sued a druggist for dispensing too large a dose of medicine, the attending physician was not only prohibited from testifying to the actual facts which he had observed, but was instructed by the learned judge to base his opinion, as an expert, solely on a set of symptoms detailed by the patient and his wife,—symptoms which the physician knew did not exist and could not have been produced by the dose in question.

"The outcome was an unjust and exorbitant verdict against the defendant."

Here, then, it is distinctly asserted that injustice was wrought by this law, or, certainly, by the interpretation of the law, and the physician was made, and in other cases is liable to be made, an unwilling accomplice in what he knows to be a piece of gross injustice.

Nor is this all: he may, by this tying up of his tongue, be made the tool of some unprincipled scamp, and by his silence seem to give assent to what he knows is a piece of downright rascality. The following corre-

spondence, which is taken from the *New York Medical Record* of October 19, 1878, will perhaps illustrate my meaning and the dangers which attend the act as it at present stands. The piece is headed "Professional Secrets and Professional Obligations," and is addressed to the editor of the *Medical Record:*

"I find such a difference of opinion between medical men as to the responsibility of a physician to his patient in certain circumstances that I am induced to ask for a brief space in the columns of the *Record* to refer to the subject.

"It is a subject of vital importance, and should be seriously considered by those whose lives are devoted to the cure and *prevention* of disease.

"A young man, while under treatment for constitutional syphilis, brought to his physician a lady suffering from some slight temporary ailment. Upon leaving the office, he remarked in effect, 'Doctor, I wish you to cure this young lady soon, as we expect to be married shortly.' The doctor took occasion privately to remonstrate very emphatically with the young man, informing him of the evil consequences which were sure to follow. The reply was, 'I cannot help it: the invitations are out, and I cannot withdraw.'

"The remonstrance was unheeded, the marriage accomplished, and now 'the most beautiful young lady' the physician had ever seen is suffering with syphilis in a severe form, the doctor having reason to fear grave, and perhaps fatal, complications. Thus, through ignorance on the part of the lady, criminality on the part of the man, and '*professional obligations*' on the part of the medical adviser, was this work accomplished."*

So far as the legal aspects of the case go, the physician was, in my belief, right, entirely right; but as regards equity, ah! that is another matter, for many of us are sadly aware that law and equity are not by any means synonymes. The law as it stands at present is a gross injustice to all concerned: it gags the mouth of the reputable physician, but permits the gabble of the charlatan. Note well, I pray you, "a person duly authorized to practise," etc. The charlatan is not "duly authorized." It does not protect the physician as a witness, for, while the law seems so to do, the astute lawyer will call upon him as an expert and get all he wants out of him, and often without any pecuniary return to the physician.

More yet. The law converts the family physician into a wolf in sheep's clothing. He knows all that goes on below the surface; he appreciates the danger, he realizes the dreadful consequences, and yet the law, as now applied, forces him into being a scoundrel. Come; put the *argumentum ad hominem.* How would those of us who have marriageable female relations like to see any one of them engaged to a man whom we knew to be diseased, and whom we could not warn her against for legal reasons or professional obligations? And after the deed is done, how would the doctor feel while looking at the wreck he had helped to make, knowing that but for the law he could have at least done his duty by giving a note of warning? In the parable of the man who fell among thieves most of us are accustomed to regard the priest and the Levite with feelings of contempt; let us as physicians, then, see that we do not by any voluntary act place ourselves in a similar position.

The Medical Society of the County of New York, so far from being satisfied with the law, to its credit be it said, instructed its delegates to request the State Society to examine into the expediency of urging the abolition of this law. What the result may be no man can say; but one thing is certain,—that in New York City many regard the law as unnecessary, injurious, and unjust.

With many apologies for intruding this long letter upon you,

I am, with great respect,
Your obedient servant,
F. R. STURGIS, M.D.

16 WEST 32D STREET, NEW YORK CITY.

* The rest of this article is omitted, as not pertinent to my argument.—F. R. S.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, JANUARY 13, 1881.

THE PRESIDENT, Dr. S. W. GROSS, in the chair.

Sarcoma of testicle. Exhibited by Dr. H. F. FORMAD.

THIS tumor was removed from a young man by Prof. Agnew, in the surgical clinic of the University Hospital, in October last. I failed to obtain a complete history of the case, and learned only the following from the gentlemen of Dr. Agnew's clinical service. The patient was about 17 years of age, and in apparent good health. The tumor developed within one year, slowly at first, but later growing more rapidly, reaching, at the time of the operation, the size of a large fist. At no time was there any pain; and the only inconvenience experienced by the patient was from the weight and the size of the tumor. The skin was not involved.

On examination, after removal, the tumor showed itself to be developed from the tissue of the left tunica vaginalis testis: the structure of the testicle was not at all involved, but the whole testicle of that side was simply pushed up into the upper part of the sac, and was much atrophied. The tumor had a thin capsule, was elastically hard in consistence, and on

section presented a white fibrillated appearance. Microscopical examination revealed the typical structure of large-celled spindle-celled sarcoma.

Dr. S. W. GROSS thought that in this particular instance the tumor had started in the connective tissue between the dartos and tunica vaginalis testis. Sarcoma may arise from the connective tissue of any part, but he considered that the site of the present one was unusual. He also related a case seen by Prof. Gross, presenting the following history. The gentleman had been operated upon in Kentucky for a sarcomatous growth, as was then thought, connected with the testicle, which organ, he stated, had been removed at the operation. Upon careful examination, Prof. Gross determined that the recurrent growth for which he had been consulted was in reality a diseased testis. The former operator had doubtless removed a growth like the present one, which resembled in form a tumor of the testis, and which probably sprang from the connective tissue. Prof. Gross, in operating for the recurrent growth, tied the cord, thus demonstrating the presence of the gland. The wound healed slowly, recurrence took place, despite the use of the actual cautery, etc., and death finally ensued.

Dr. H. F. FORMAD had had no opportunities of observing patients affected with sarcoma of the testis, but it could not be a very rare disease, since he had had sent to him for examination in the past few years no less than nine specimens. Of these, two sprang from the connective tissue; four were of the round-celled variety, and were associated with more or less cartilage; two consisted of ordinary spindle-cells; while one was of the large spindle-celled variety. One of the specimens seemed to have had its origin in an inflammation set up by the injection of iodine into a tumor of the testis. Dr. C. T. Hunter had been consulted some few months subsequent to this, when he found that a number of large nodular growths had formed, which induced him to castrate the man. Microscopically these masses were seen to be sarcomatous, while the bulk of the tumor consisted merely of new inflammatory tissue. In this case, thirteen months after the operation the glands of the neck became involved. In another case, where he had been requested to examine, post mortem, the supposed tuberculous testis of a man dead from phthisis, he had, to his surprise, found that the organ was affected with sarcoma.

Dr. S. W. GROSS asked Dr. Formad whether in his examinations of the round-celled variety he had ever found any traces of gland-structure.

Dr. FORMAD replied that he had in one case.

Dr. J. H. BRINTON recalled the case of a prominent gentleman of this city upon whom he had operated some three or four years back for sarcoma of the testis. The wound healed readily, but in nine or ten weeks the retro-peritoneal glands became involved, a little later those of the neck, and death rapidly occurred.

Sarcoma of testicle. Exhibited by Dr. J. H. BRINTON.

J. L., æt. 40 years, a farmer by occupation, came under my care in May, 1880. He asserted that the enlargement of his testicle had commenced three years previously. No history of traumatism or other exciting cause could be ascertained. Castration was performed May 5, 1880, and the patient died of pyæmia, June 1, 1880.

A microscopic examination by Dr. S. W. Gross showed that the tumor consisted of large spindle-cells, with here and there a fibrillated intercellular substance. The seminal tubules were dilated, deformed, and lined with columnar epithelium.

Dr. S. W. GROSS then read a paper, accompanied by the specimens, upon "Two Cases of Round-Celled Sarcoma of the Testicle, with Local Recurrence and Secondary Deposits after Castration."

Case I.—A laborer, 35 years of age, was sent to me on the 8th of June, 1880, by Dr. T. W. Taylor, of Kennett Square, on account of a smooth and uniform enlargement of the right testis, which was of the size of a large cocoanut, of an elastic and here and there pseudo-fluctuating consistence, and the seat of occasional pain. About three years and a half previously the testis became greatly swollen from the man being jammed between the wheels of a wagon; but the inflammation gradually subsided, leaving, however, the organ about double the size of its fellow. Fifteen months ago it began to increase, until it finally attained the volume above mentioned. After castration the albuginea was seen to be pervaded by immense tortuous veins; but that tunic was not thickened, nor was the cord involved. Section was attended with the escape of a dirty yellowish fluid, and the cut surfaces were of a translucent grayish tint, and mottled by large areas of blood-stained broken-down tissue and by small spots of caseous degeneration, and they also contained a few cysts. The entire upper portion of the tumor was converted into a cheesy mass as large as a billiard-ball. Microscopical examination disclosed a small round-celled tissue, the intercellular substance of which was granular. There was no trace of seminal tubules.

At the expiration of three months the man began to complain of pain in the belly, and soon afterwards Dr. Taylor discovered a tumor as large as an orange just below and to the right of the umbilicus. The suffering soon became severe and constant; temporary paralysis and œdema of the lower extremities ensued; the bowels could only be moved by purgatives; and nausea and vomiting, which came on every afternoon, continued throughout the night unless he was fully under the

influence of morphia. When I saw him, on December 4, the symptoms had not abated. He was growing thin, had no appetite, and his face was becoming icterode. A small recurrent growth occupied the scrotum. The abdominal tumor, which I was informed had doubled in size in the last ten days, was as large as a child's head, filling the right lumbar and nearly the entire umbilical region, and had an elastic feel. Exploration of the chest disclosed the physical signs of secondary deposits in the upper lobe of the right lung. Death ensued on the 20th of December; but an examination of the body was refused.

Case II.—A farmer, 33 years of age, consulted Prof. W. H. Pancoast on account of a tumor of the right testis, which he said was of four years' duration and had developed in consequence of a blow received in climbing a fence. Its consistence was elastic, its outline smooth and pyriform, and its volume equalled that of a small cocoanut.

The organ was removed in the usual way on the 24th of February, 1880. The cut surfaces had a medullary aspect, and the minute structure was that of a granulation sarcoma, with entire disappearance of the seminal tubules.

The wound closed promptly, but in two months there was recurrence in the stump of the cord. Early in September the growth had attained the size of a fist, when Dr. Pancoast removed it by laying open the inguinal canal and ligating the cord at the internal ring. The wound healed in four weeks, but on his return to the hospital of the Jefferson Medical College, October 22, it was found to have opened, and there was a fungous mass in the groin as large as an orange, which was scraped away, and the parts freely touched with chloride of zinc. Shortly afterwards a tolerably firm and painful tumor was detected in the retroperitoneal glands of the corresponding side, on which account nothing further was done in the way of surgical interference. At the date of his discharge, December 1, the abdominal tumor was as large as a child's head, and the glands of the left supraclavicular fossa were as big as an egg. The man was decidedly anæmic, and he had been suffering for several weeks from gastralgia, loss of appetite, and almost constant nausea and vomiting.

Remarks.—The cases which have been presented to the Society this evening possess many characters in common, and two, namely, that of Dr. Pancoast and my own, are especially interesting as being examples of reproduction of the disease in the abdominal lymphatic glands and of local recurrence shortly after operation.

Implication of the glands is a remarkable feature in connection with sarcoma of the testis when considered in relation to the immunity of the glands in sarcoma of other organs. In sarcoma of the breast, for example, as I have pointed out in my "Treatise on Tumors of the Mammary Gland," involvement of the axillary glands is not met with during life, nor does post-mortem inspection disclose that the deep glands are converted into metastatic tumors. In the disease under consideration, on the other hand, secondary glandular growths are more common than they are in carcinoma of the testis, so that they afford no aid in the differential diagnosis, as is the case in carcinoma and sarcoma of other organs. From an examination of 40 examples of sarcoma of the testis which I have collected from various sources, I find that the histories are complete in 26. Of these, three were well after castration for an average period of six years, two being free from recurrence for two years, and one for fourteen years. Three pursued a natural course, and post-mortem inspection showed secondary tumors in the lumbar glands, bones, and subcutaneous tissue in one, and visceral tumors, without glandular enlargement, in two. Twenty were castrated; of these, one—the case of Pancoast—is still living, with local recurrence and enlargement of the lumbar and supraclavicular glands, and 19 are dead, with glandular implication and visceral deposits, especially in the lungs and osseous system, in 16. Hence, of the 26 cases, in 18, or 69 per cent., the retroperitoneal glands were the seat of secondary deposits; and I find that they are involved in 62 per cent. of the examples of carcinoma. In several of the cases the absence of glandular affection may be explained, as is pointed out by Mr. Butlin in a valuable paper on the subject in the *Lancet*, August 28, 1880, by the short duration of the disease.

The great frequency of the development of secondary growths in the retroperitoneal glands into which the lymphatics of the testis empty, tends to show that sarcóma originates from the endothelial cells of the large lymph spaces which surround the seminal tubules, rather than from the membrana propria of the tubules.

Local reproduction in the stump of the cord or in the adjacent tissues, which constitutes the second interesting feature of the disease, is so uncommon that it was met with in only five of the twenty-three cases in which the histories are complete after operation.

As specimens of sarcoma of the testis have been so rarely exhibited to the Society, I take this occasion to analyze still further the cases which I have collated and to compare them with those of carcinoma. Seventy-five per cent. of all examples of sarcoma occur before the forty-first year, and 25 per cent. before the eleventh year, three having been observed respectively at eight, ten, and eleven months. Fifty-six per cent. of all cases of carcinoma are met with before the age of 41, and 6 per cent. before the age of 11. In sarcoma the epididymis is more early implicated, its growth is more rapid, and its volume is greater; the

scrotum is not adherent, and it ulcerates in only 3 per cent. of all instances; and the cord is involved in the disease in 35 per cent. In carcinoma the scrotum is adherent in 36 per cent. and ulcerated in 9 per cent. of all examples, and the cord is implicated in 63 per cent. of all specimens. In sarcoma the tunica albuginea is rarely thickened, while that occurrence is the rule in carcinoma. In the former affection both testes are not uncommonly affected, while one alone is involved in the latter disease. Finally, the presence of cartilage is so frequent in sarcoma, and so rare in carcinoma, that it goes far to establish the diagnosis.

Of the 40 cases, 22 were of the round-celled, 15 of the spindle-celled, and 3 of the mixed variety.

The prognosis of sarcoma is eminently unfavorable. Thus, of the three cases which pursued a natural course the average duration of life was less than ten months. Of twenty-three patients subjected to operation, three were living at the date of the last reports for an average period of six years (and, strange to say, they belonged to the round-celled variety), one was still alive with local and general reproduction, and nineteen died of generalization of the disease, their average life having been twenty-seven months. Hence castration not only prolongs life, but may effect a cure. The total duration of life from the first observation of the disease until its termination after operation averaged eighteen months for the round-celled and twenty-eight months for the spindle-celled variety; and the former was followed by metastatic tumors in eighteen per cent. more of instances than was the latter.

REVIEWS AND BOOK NOTICES.

LECTURES ON THE SURGICAL DISORDERS OF THE URINARY ORGANS. DELIVERED AT THE LIVERPOOL ROYAL INFIRMARY. By REGINALD HARRISON, F.R.C.S., Surgeon to the Infirmary, formerly Lecturer on Anatomy and Surgery at the School of Medicine, and Surgeon to the Liverpool Northern Hospital. Second Edition, considerably Enlarged. London, Churchill; Liverpool, Adam Holden. Octavo, pp. 398. 1880.

In the volume before us, consisting of thirty lectures upon the surgical disorders of the urinary organs delivered at the Liverpool Royal Infirmary, Mr. Harrison has greatly extended and improved the former edition of his work. The first eleven lectures are devoted to the study of urethral stricture, its pathology, consequences, and treatment, and these matters have been discussed by the author in an essentially practical manner. The key to his treatment is found in the statement —which is, we think, concurred in by the great majority of surgeons—that when once a stricture has become cicatricial in its character its nature may be palliated or adapted, but the absolute integrity of the urethra can never be absolutely restored. The inconveniences of the scar may be moderated, but the scar itself cannot be obliterated.

The term stricture the author reserves to what is ordinarily spoken of as organic stricture; spasm and inflammation he regards simply as superadded conditions. Of stricture he makes two forms,—the mucous and submucous,—the former being limited to the lining membrane of the urethra, the latter to the tissues outside of the mucous membrane. The indolent, irritable, contractile, and hemorrhagic strictures are carefully dwelt upon, the treatment of the irritable form being best conducted by Holt's method under anæsthesia, while that of the contractile variety can be most effectually accomplished by section,—urethrotomy either external or internal. For the other forms of stricture Mr. Harrison counsels gradual dilatation, employing for that purpose filiform, flexible, and metallic bougies, and availing himself, in proper cases, of the plan of continuous dilatation. At page 115 the author speaks of Dr. Otis's method of treatment, with which our readers are so familiar. He states, however, that his observation is not favorable to this method, and adds, "I have already expressed my belief that stricture in its earliest form is curable, provided that dilatation by bougies is sufficiently carried out. Hence I reserve for internal urethrotomy cases which are not likely to be benefited by dilatation, and these, as far as my experience goes, do not include strictures in their early stage."

The lecture upon the surgical anatomy of the urethra is very valuable, and the attachments of the various fasciæ are carefully given, and their influence in guiding urinary extravasations is lucidly set forth, and well illustrated by the cut at page 29. The fourth lecture is devoted to the examination of the urine, its acidity, alkalinity, the occurrence of ammoniacal decomposition, and the resulting therapeutical suggestions. Urethral fever forms the subject of the sixth lecture. In the opinion of the author, this condition depends, to a greater or less extent, upon renal engorgement or thrombosis, and its treatment may be best conducted by remedies looking to the restoration of the renal excretion. He advises, therefore, vapor baths, hot baths, blanketing, dry cupping, and other local means of that nature, and, internally, the use of the infusion of digitalis, as suggested by Dr. Gouley, of New York. He adds, moreover, that prevention is better than cure, and expresses his belief that if after every operation likely to cause urethral fever a free state of diaphoresis should be established by hot blankets and suitable temperature we should hear but little of urethral fever.

At page 95 we find a most important statement, with which our own experience largely concurs,—namely, that urethral fever depends upon nerve-shock, and that where anæsthetics have been used for catheterism there is almost a complete exemption from this disagreeable condition. In the lecture devoted to retention of urine from stricture the use of the filiform bougie and turetted catheter is advised before the surgeon arrives at the conclusion that the stricture is for the time impassable. We think our author might in this matter have gone farther than he does, and we would suggest, from our own experience, that in the worst cases of retention it is probably always possible to introduce, under anæsthesia, a whalebone filiform bougie. If such an instrument be once carried through the stricture and into the bladder, the urine will surely escape by its side sufficiently to relieve the bladder for the time, and, in the course of a few hours, to evacuate the organ entirely. We believe that the use of the aspirator is rarely called for, and certainly not until the means mentioned have been fairly tried.

We are unable, within the limits assigned to this short notice, to follow our author in his most interesting remarks upon internal, external, and subcutaneous urethrotomy, urethral abscess, extravasation of urine, perineal fistulæ, and foreign bodies in the urethra and bladder. We cannot forbear, however, from noticing the chapter upon irritable bladder, which we especially recommend to the consideration of our readers. The lectures upon hypertrophy of the prostate and its treatment are also well worthy of perusal. In the treatment of obstructions of this nature near the neck of the bladder Mercier's treatment by internal incision of the prostate is alluded to, but we are told that it can scarcely be said "at present to have a place in the operative surgery of the urinary organs." The use of ergot, as advised by Dr. Atlee, of this city, in cases of difficult micturition in connection with enlarged prostate, is favorably spoken of. The remainder of the work is occupied with the study of calculous disorders, lithotomy, lithotrity, lithoplaxy (which the author highly esteems), the surgery of the kidney, vesical and prostatic tumors, and sundry other affections.

All of these topics are treated of in a practical manner, and every reader of these excellent lectures will feel, we are sure, that his time has not been misspent. The author has, we think, succeeded in making a most useful book, one to which any surgeon may turn with pleasure and profit. In some instances, perhaps, his views may be peculiar, but they are his own, and, coming from one who has thought much and has had much experience in the active practice of the surgery of the urinary organs, they must command respect. We sincerely wish this book the success it deserves, and we congratulate the author upon the result of his labors in preparing this new edition.

HAND-BOOK FOR CORONERS. Containing a Digest of all the Laws in the Thirty-Eight States of the Union, together with a Historical *Résumé* from the Earliest Period to the Present Time, a Guide to the Physician in Post-Mortem Examinations, and Valuable Miscellaneous Matter never before collated. By JOHN G. LEE, M.D., Coroner's Physician of the City and County of Philadelphia, Pa. Published by William Brotherhead, Agent, 129 South Thirteenth Street, Philadelphia, 1881. 8vo, pp. 288.

The author of this little volume, with its somewhat elongated title, announces in his preface that he "makes no pretensions to originality," but that his "almost sole duty has consisted in the collection, selection, and arrangement of the most interesting material at his command." This, of necessity, disarms all criticism of the book as an original production. The "material" thus used appears to have been judiciously employed for the purposes designated. The author gives us a pretty full history of "coroner's law" from its earliest inception, in the time of England's great King Alfred, down to the present era, including the laws of all the different States of our own country. In fact, more than half of the volume consists of a detail of these latter State laws, which exhibit a general similarity of character, while at the same time showing some points of difference: thus, in some of the States the coroner's law is more stringent than in others, and there is a notable diversity in the *fees* of the office. These latter fluctuate between one dollar (for an inquest) in West Virginia and twenty-five dollars in Louisiana. In the cities of Philadelphia and New York, instead of a fee paid for each separate inquest, there has within a few years been substituted a regular salary for the coroner,—six thousand dollars in the former city and five thousand dollars in the latter, exclusive of contingent expenses.

The chapter on the "Coroner's Physician" contains much interesting matter, but only the usual subjects discussed in the standard works of legal medicine,—such as medical evidence, expert testimony (in the latter, by the way, the author is mistaken when he asserts that in Pennsylvania the expert may *legally* demand an extra compensation), the mode of making autopsies, the signs of death, etc.,—all of which, however, are given with sufficient precision and judgment. The book concludes with a series of anecdotes—some of them quite racy—of coroners and their juries. G.

PRACTICAL AND ANALYTICAL CHEMISTRY. By FRANK CLOWES, D.S.C. Lond. H. C. Lea's Son & Co., Philadelphia.

This small treatise is a hand-book for use in the laboratory, detailing a long series of

experiments, analyses, etc., for use by students of chemistry. Whilst very valuable in the position for which it is intended, to the busy doctor of to-day the manual is chiefly interesting as an evidence of progress and as provocative of energy towards the medical students of the present. The book is neatly gotten up as a reprint from the third London edition.

ROCKY MOUNTAIN HEALTH-RESORTS. An Analytical Study of High Altitudes in Relation to the Arrest of Chronic Pulmonary Disease. By CHARLES DENISON, A.M., M.D., etc. Second Edition. Boston, Houghton, Mifflin & Co., 1881. Pamphlet, 12mo, pp. 192.

Dr. Denison's personal and professional experience in the Rocky Mountain region has induced him to write this little book, with the view of guiding both the invalid and the patient in the choice of a health-resort. After an introductory chapter on consumption and its prevalence, the author goes on to discuss climates of low, medium, and high altitudes in successive chapters, and then continues by a full description of the climatic characters of the Rocky Mountain region, its mineral springs, etc., the remaining chapters being devoted to the consideration of the various disease-conditions apt to be influenced by climate, together with the effect which the Rocky Mountain climate in particular produces on those conditions. The two last chapters are devoted to precautionary measures, hints for invalids, ranch life, camping out, etc. The book is one of the most valuable which has yet appeared on the subject of which it treats.

JOHN HUNTER AND HIS PUPILS. By S. D. GROSS, M.D. Philadelphia, Presley Blakiston, 1881.

This is a very entertaining and thoughtful account of the life of John Hunter, with notices of some of his most eminent pupils, the whole being comprised in a book of one hundred and six pages and prefaced by a very excellent phototype of Reynolds's famous portrait of Hunter. The study is worthy of both its author and its subject.

DIAGRAMS OF THE NERVES OF THE HUMAN BODY. By WILLIAM HENRY FLOWER, F.R.S. Third Edition. Presley Blakiston, Philadelphia, 1881.

We are very well pleased to announce a new edition of this practical and well-known brochure. The diagrams are very nearly the same as in the last edition, having been only amended in a few points.

CHLORATE OF POTASSIUM IN MARASMUS.—Dr. Herbert Sum has used this drug in two- or three-grain doses four times daily in an infant a few weeks old with very good result. —*British Medical Journal.*

GLEANINGS FROM EXCHANGES.

DANGERS OF UTERINE MANIPULATIONS AND OPERATIONS.—Dr. George J. Engleman, in a paper read before the State Medical Society of Missouri, referred to the following instructive cases. The first was of a married lady suffering with retroversion and syphilitic ulceration of the os. During the treatment the uterus had been frequently and easily replaced by means of the sound, and held in place by cotton tampons in the posterior cul-de-sac. After an interval of several months the patient again consulted her physician for pains in back and thighs following unusual exertion. Retroversion, but no inflammation or erosion, was found. The uterus was replaced, as usual, after the introduction of the sound, and the physician advised her to lie down quietly until he should see her upon the following day. This was at 11 A.M. At 4 P.M. he was hastily summoned, and found his patient in a state of great nervous prostration, with high fever, temperature 103°–104°, headache, nausea, and vomiting. A severe chill, lasting from 2 P.M. until 2.30 P.M., had preceded the fever. Physical examination revealed considerable abdominal distention and tenderness, with some slight tenderness about the cervix. These symptoms subsided within forty-eight hours under a treatment of opium with large doses of quinine, and steady improvement followed. The sound, as a repositor, has never been a very safe instrument.

In a second case, a patient suffering from retroversion and chronic endometritis, the uterus was movable, easily restored, and kept in position by a tampon of cotton soaked in glycerin, and every six days an application of the compound tincture of iodine was made to the womb. Two or three hours after one of these applications the patient was seized with violent pelvic pains in the region of the uterus and ovaries; they were intense, but not accompanied by any decided evidences of inflammation, although there was some elevation of temperature, tenderness on pressure, nausea, and vomiting. Within thirty-six hours the symptoms subsided, upon the use of quinine and opium, and hot applications to the abdomen. Dr. Paul F. Munde, of New York, told Dr. Engleman that he had in two instances only, out of several thousand applications of iodine which he had made, seen cellulitis arise.

The third case was that of a woman of 23, who was placed upon treatment for slight ulceration about the os uteri and a retroversion, seemingly the result of chronic metritis. During nine months of treatment various remedies were used, such as vaginal injections with sulphate of zinc, acetate of lead, and tannin. Applications to the ulcerated portion of the cervix were made with nitrate of silver and dilute acid nitrate of mercury. The latter had a good effect, but was discontinued, and

tincture of iodine substituted. The patient was rapidly improving, both locally and constitutionally, when, after one of these applications of iodine to the cervix,—which were made every two weeks without entering into the cervical canal,—she was attacked with peritonitis, and soon died, without a known cause to account for the fatal issue.

The fourth case was one of death from intra-uterine injection of iodine, made for the purpose of checking hemorrhage.

A fifth case was one of metro-peritonitis and death following an intra-uterine injection of a warm and dilute solution of tinct. ferri chloridi.

A sixth case was one of intense pelvic pain and threatened peritonitis following the use of a Davidson syringe.

Apropos of this, Dr. Engleman says, "In order to obviate the dangers and the discomforts arising from vaginal injections as ordinarily used, I advise my patients (1) to plug the central opening of the vaginal attachment; (2) to assume the semi-recumbent, better the recumbent, position, with knees drawn up; (3) never to use a strong current, whether by the fountain- or the bulb-syringe."

After adding several cases of severe accidents and death following the use of sponge-tents, Dr. Engleman remarks, "Care and cleanliness, if not Listerism, are necessary in even the most trifling uterine operations, and the strictest surveillance should be exercised over the patient during the after-treatment, even if this consists in nothing more than rest—absolute rest—and cleanliness. This is all the more necessary as a patient after a slight operation may suffer neither fever nor pain; on the contrary, the happy effect of the operation may already have shown itself: she is free from all the annoying aches and pains of which she complained before the operation, and considers herself accordingly well and at liberty to move about as she pleases.

"Rest and careful attention during the after-treatment are extremely important features; and yet, with all care, dangerous and fatal results may occur. Very few of the text-books which you may consult before attempting an operation will tell you anything of its dangers, unless it be an ovariotomy or a similarly serious undertaking. They will tell you how to operate, but will not detail the minute precautions to be observed in the operation, or counsel you how careful to be of the patient after she has been operated on, as she ceases to be an object of interest when once the aspiring surgeon has cut."—*American Medical Journal.*

A New Method of Operation for Ranula.—Dr. Krabbel (*Centralblatt f. Chirurgie*, No. 37, 1880) reports the successful removal of a large sublingual cyst by a method not hitherto described. It is well known that, apart from complete extirpation, the ordinary methods, such as puncture, the injection of irritant fluids, partial excision, etc., by no means always result in a complete cure. Krabbel recently had occasion to observe a large ranula, in which previous remedial measures had been unsuccessful. He adopted a plan of operative procedure which was suggested to him by a consideration of Volkmann's method of radical operation for hydrocele. Accordingly, the sac of the cyst, which formed an externally visible prominence, was exposed by an incision from without, and an oval piece of its wall excised. The cyst-wall was now united by silk sutures with the integument; then a second piece was incised from within, and the walls similarly united with the buccal mucous membrane. A drainage-tube was inserted, and carbolic irrigation practised. All the dressings were antiseptic. Eight days later the drainage-tube was removed, and the wound soon closed by granulation, the collapsed cyst-walls becoming united by adhesive inflammation. The external cicatrix was quite inconspicuous, and internally there only remained a little hardening to indicate the site of the former cyst.—*Allg. Med. Cent. Zeit.*, September 22, 1880; *New York Medical Record.*

Actions and Uses of certain Remedies employed in Bronchitis and Phthisis.—In an article on this subject (*Lancet*, vol. i., 1881, p. 4) Dr. T. Lauder Brunton says that as coughing is a reflex act, excited by irritation applied to a sensory nerve and reacting through a nerve-centre upon the respiratory muscles, it is obvious that it may be lessened either by removing the source of irritation or by diminishing the excitability of the nervous mechanism through which it acts. Both methods are employed in medicine. One of the commonest is that of lessening irritation by the use of glutinous and saccharine substances. These probably act by soothing that part of the irritation which is situated about the root of the tongue and the fauces, thus relieving the cough, though the irritation in the bronchial tubes or lung may remain as before. The power of substances to relieve cough depends, no doubt, to a great extent either on their covering the inflamed and irritated surface directly with a mucilaginous coat and thus protecting it from the action of the air or from irritation by other substances passing over it, or by exciting an increased flow of saliva or mucus, which has the same effect. Sedatives, as opium, hyoscyamus, and chloroform, have a certain amount of local action on the peripheral ends of sensory nerves and lessen their sensibility to impressions. This action, though slight, is increased when they are given in a mucilaginous vehicle. Of course there is also a less direct action through absorption by the stomach.

When the source of irritation is in the afferent nerves of the bronchi or of the lung itself, mucilaginous and sedative drinks are of course useless. Here vapor of conium or hydrocyanic acid tends to lessen irritability. Other inhalations, as of spray of ipecac and

essential oils and terebinthinate substances, alter the nutrition of the mucous membrane in such a way as to diminish the irritation which the abnormal condition of the membrane exerts upon the nerves. In laryngeal phthisis local applications with a brush or by blowing powders directly on the diseased surface are the best means. A useful application is a powder of one-sixth grain of morphia to two grains of starch. This mixture is placed in a tube and blown down the throat at the moment the patient takes a deep inspiration. The following prescription of Dr. Warburton Begbie is analyzed by Dr. Brunton:

℞ Liq. morphiæ hydrochlorat.,
Acidi hydrocyanici,
Chloroformi, āā ℥xviij;
Spiritus chloroformi,
Acidi nitrici dil., āā ʒj;
Glycerinæ, ʒiij;
Infus. cascarillæ
(seu infus. quassiæ), ʒij.—M.

A sixth part to be taken three or four times a day.

Here the sedatives—morphia, hydrocyanic acid, and chloroform—tend to lessen the excitability of the respiratory centre; the glycerin tends to retain the sedatives in longer contact with the throat, and acts also to some extent as a nutrient; and the nitric acid and bitter are supposed to have a tonic effect on the stomach. In what way this tonic effect is produced we cannot at present say; but we may imagine that they will in some way partially counteract the effect of the congestion which the cough produces, and, exciting appetite, will counteract the influence of the morphia. Nitric acid has also, as Dr. Brunton points out, a definite effect on the secretions of the lung themselves. Considering those drugs which tend to lessen congestion, Dr. Brunton mentions digitalis, and gives the following prescription from Beasley as used by Sir A. Crichton:

℞ Succi limonis, ʒss;
Potassii carbonat. ad saturand.;
Decoct. sarsaparillæ, ʒx;
Tinct. digitalis, ℥x ad xxx;
Mucilag. acaciæ, ʒx.—M.

To be taken every sixth hour. The tincture of digitalis here tends to contract the vessels, diminish pulmonary congestion, and lessen cough. The potash renders the pulmonary secretion more fluid and abundant. Warm food, as beef-tea, Dr. Brunton says, is a good expectorant, as also is cod-liver oil. Ice, hydrocyanic acid, and alum are recommended in the vomiting of phthisis.

Relations of Goitre to Pregnancy and Generative Derangements of Women.—Dr. Edward W. Jenks, in a very interesting article in the *American Journal of Obstetrics* for January, speaks of the comparative frequency of enlargement of the thyroid among women, and calls attention to the relation between this enlargement and certain changes in the generative organs. The connection has not until recently been touched upon by medical writers except in the most cursory manner. Regarding the etiology of goitre, its appearance, in countries where it is endemic, is coincident in most cases with the arrival of puberty. It is also probable that puberty may enter to some extent into the causation of sporadic goitre. When menstruation is once established, it frequently happens that at each return of the menstrual period the thyroid gland becomes the seat of a fluxion, more or less marked, which disappears with the cessation of the catamenia. Dysmenorrhœa and amenorrhœa sometimes influence the rapid development of goitrous tumors. These are generally firm and elastic, and may be extremely painful or quite insensible on pressure, but are almost always the seat of much discomfort during menstruation. They are, as a rule, quite amenable to treatment, and those which come most rapidly are often the first to disappear, sometimes going spontaneously.

Of all the goitres which have connection with the uterine functions by far the most numerous are those which are produced or increased by pregnancy and labor. These are not usually dangerous; although fatal cases have been reported. One form of goitre may occur suddenly in the middle of labor. After dealing with the pathology and diagnosis of thyroid tumors, Dr. Jenks goes on to speak of their treatment. First, he recommends a change of climate to a country where goitre is not endemic, and, second, a strict observance of hygienic and dietetic laws. As to medicines, iodine stands first. Interstitial injections with the following solution—iodide of potassium, one gramme; tincture of iodine, twenty cubic centimetres; distilled water, forty cubic centimetres—may also be employed. The strength of this solution may be altered by increasing or diminishing the amount of the tincture of iodine to suit the exigencies of the case. Other preparations of iodine may be used. Ordinarily a single injection suffices. Alcohol is also used in the same way. Perchloride of iron injections are used in vascular goitres, also chloride of zinc solution. Digitalis, with ergot, quinia, and iron, is recommended for internal use, and electricity has been highly recommended by several authorities. Prof. Pepper urges hypodermic injections of ergotin. A solution of ninety-six grains to the ounce is made, and fifty to seventy-five centigrammes of this may be injected every two or three days. Dr. Jenks also details various surgical operations for the relief of the affection.

Tansy-Poisoning.—Dr. Gallaher (*Pittsburg Medical Journal*, 1881, p. 22) gives the case of a patient who had taken an infusion of perhaps half an ounce of the dry herb one night before going to bed. Vomiting and purging ensued within a few hours, but in the

morning the patient felt better. By three o'clock in the afternoon, however, the vomiting and purging had recurred, together with intense abdominal pain. These symptoms continued until two the next morning, with thirst, great pain in the epigastric and umbilical region, shallow and rapid breathing, and failure of the pulse. There were neither convulsions, coma, nor paralysis. The patient's intellect was clear. She died twenty-six hours after taking the tansy.

Dr. Gallaher also gives the following case. He was called at twelve o'clock at night to a lady who had taken the oil of tansy instead of the infusion. She had been taking this substance in small doses without effect—that is, to bring on her menses—for several days, but, finding such doses inoperative, concluded to take a larger amount. Nearly half a teaspoonful was accordingly taken at about ten o'clock P.M., when about retiring. Before twelve the same night—that is, two hours after taking the oil—she was awakened by a dreadful burning and pain in the stomach and ringing of the ears. When the doctor arrived, she was cold, and for a time pulseless. An emetic of ipecac speedily evacuated the stomach, when she felt better. In a short time there was a restoration to usual health, without a return of the monthly flow.

POISONING FROM ANILINE.—Dr. Merklen reports (*Medical Press and Circular*, 1880, p. 498) the following case coming under his notice:

The toxic effect of aniline is better known by experiments on animals than by the effects of the poison observed in man. Those working in aniline-factories may exhibit the phenomena of chronic poisoning resulting from the absorption of the substance by the respiratory passages in the form of either vapor or dust; acute poisoning is rare. In the following case one hundred to one hundred and twenty grammes of pure aniline were swallowed in a liquid state: this method of absorption, with the symptoms caused by the poison, and its prompt cure, constitute the interest of the case.

A workman in a chemical factory at Clichy, on July 11, swallowed at 8 A.M. from one hundred to one hundred and twenty grammes of a mixture of aniline and toluidine, mistaking it for coffee. In spite of this he went to work as usual, without telling any one, and it was not till a quarter to ten—that is, an hour and three-quarters after the swallowing of the poison—that his fellow-workmen saw that he was stupid and motionless. Being interrogated, he told them the mistake he had made, and complained of a little headache. M. Gundelach, the chemist to the establishment, who has supplied most of these details, was immediately called, and administered .05 centigramme of emetic; the effect of the medicine was assisted by introducing the finger into the pharynx and administering large quantities of warm water. Under this treatment abundant vomiting was produced, composed of some food, water, and yellowish coloring-matter, probably unabsorbed aniline. The patient was then put to bed. About twenty minutes afterwards serious nervous phenomena appeared. The patient lost consciousness, fell into a state of coma, and appeared in a condition of general resolution, the head fallen back, lips black, face purple. Then there was contraction of the facial muscles, *risus sardonicus*, and trismus, which only permitted the introduction into the mouth of a few drops of milk with great difficulty. At this time there was no convulsion, no contraction of the limbs, pulse very feeble, coldness. This was about half-past ten, two hours and a half after the taking of the aniline. All means were used to introduce some alcohol: at length the patient swallowed a few drops, and immediately seemed to awake. This remission was taken advantage of to make him swallow a larger quantity of alcohol, and of tea with alcohol. To overcome the cold, the patient was warmed with coverings and bottles of hot water and the whole body rubbed with camphorated spirit. He regained consciousness, and vomiting returned. At half-past twelve two enemata with oil were given, without result. About two o'clock the patient again lost consciousness; the pulse became weak, cyanosis remained, though less marked than at first. About three o'clock appeared clonic convulsions of the limbs, with complete loss of consciousness; the contraction of the face and the maxilla had disappeared.

At this time the patient was taken to the Hospital Beaujon, where he was received under the care of Dr. Millard. The interne, on arrival, found him in a state of profound coma; the pupils dilated, acting little under the influence of light. Catheterism gave exit to about two hundred grammes of dark brown-colored urine. Death was considered imminent. The coma lasted all night, interrupted frequently by convulsive attacks in the limbs. During all this time the face was purple.

Next morning, at the time of the visit, the patient was awake, and complained only of severe headache; the face, especially the lips, still slightly cyanosed. No other abnormal phenomenon. Sensibility normal everywhere except in the velum palati and the pharynx, where tickling produced no reflex action. No paralysis. The patient had passed urine spontaneously. This was very dark in color, albuminous, and gave a strong alkaline reaction, while that of the evening was acid and not albuminous. No pain in the belly; no stool yet since the accident. A strong odor of aniline proceeded from the patient's bed, apparently coming from his clothing. Ordered milk, purgative enema, bath. The next day and succeeding days the headache disappeared. Urine still dark, but very slightly albuminous. The patient left the hospital after

five or six days, with no symptom remaining but the anæsthesia of the soft palate.

The blood examined the day after the accident showed nothing abnormal in the shape of the red corpuscles. Number, 4,200,000. Temperature on that day, 37.6 C. (99° Fahr.). The urine was analyzed by M. Gundelach: that of the evening only contained aniline unchanged; there was no trace of it in that of the morning, the alkalinity of which was due to carbonate of ammonium.

Remarks.—There are some peculiarities in this case. In the first place, in spite of the assertions of the patient, it can scarcely be allowed that he had swallowed more than one hundred grammes of aniline. We know, indeed, that fifteen or twenty drops are sufficient to cause in a rabbit toxic, often fatal, effects: it is probable that the patient immediately rejected some of the liquid swallowed, owing to its slight causticity. The first effects of the poison were not shown till about two hours after its introduction, and these effects progressed to coma and convulsions, as in experiments on animals. The most recent of these experiments, made by Leloir, prove that aniline causes convulsions and asphyxia by acting primarily on the hæmoglobin of the blood, of which it diminishes the absorbent power. We can understand from this why the effects do not appear more rapidly.

As special troubles we recall the transitory albuminuria, well in accord with the hypothesis of an alteration of the blood, and the anæsthesia of the velum, which remained even when the patient left the hospital. The troubles of sensibility in aniline-poisoning have been cited by several authors, recently by Grandhomme, who in patients poisoned by aniline vapor found absolute cutaneous anæsthesia. In our patient the anæsthesia was localized in the throat, but was persistent.

The treatment of this form of poisoning consists simply in the administration of stimulants with cutaneous revulsives. It is necessary to add evacuants in those special cases where the poison has been introduced by the digestive passages.

Recent Remedies.—Dr. James Sawyer (*Practitioner*, January, 1881, p. 39) thinks that much may be gained by practising physicians if each one will give his experience of such remedies as he has employed in his own practice. Dr. Sawyer adds his own experience:

Fuchsin he has used in doses of one grain thrice daily in albuminuria probably dependent upon chronic contracting kidney. He gives the remedy in pills, one-grain doses, made up with extract of gentian, to which may be added a little carbonate of iron or reduced iron. It colors the fæces and urine pink, but produces no subjective symptoms. He considers it the best remedy he has used in renal albuminuria.

Nitro-glycerin Dr. Sawyer has used in two cases of angina pectoris. In the first case, an elderly man with a fatty heart, no apparent benefit ensued. In the second case, that of a middle-aged man with chronic valvulitis and aortic stenosis and incompetence, marked relief was obtained. Dr. Sawyer does not mention the dose given, but he reminds us that Dr. Murrell, who introduced the remedy, gives one-drop doses of a one per cent. alcoholic solution in half an ounce of water thrice daily. The dose may be increased gradually up to fifteen minims.

Salicylate of sodium has been employed with success by Dr. Sawyer in diabetes. He gives it in a mixture containing fifteen grains of the salt with seven minims of tincture of opium thrice daily. One of his patients has been practically cured by this treatment, while others have been much benefited. He does not make any dietetic restrictions.

Ingluvin Dr. Sawyer thinks will prove a valuable addition to our materia medica. He has found it useful in atonic dyspepsia in doses of ten grains thrice daily, in powder sprinkled on bread, immediately after meals. In one case of the obstinate vomiting of pregnancy ingluvin was used with perfect success.

Milk-Diet in Heart Diseases.—Prof. Potain concludes a somewhat lengthy paper on this subject as follows. The "*régime lacté*" is particularly efficacious in secondary cardiac disease,—that is, in simple hypertrophy or dilatation of renal or gastric origin. In one case the milk-diet favorably alters the condition of the kidneys, and in the other the gastric state. But, in order to give these organs the needed repose, it appears essential to make the milk-diet absolute, and to prolong it for a greater or less length of time. A good effect of this regimen is also observable in those cases of simple reflex palpitation which depend upon gastric disturbance. In dropsy accompanying secondary renal lesions, the diuretic action of milk may act advantageously. This exclusive milk-diet can, however, be persisted in only when the system readily tolerates it.—*La Tribune Médicale*, September 19, 1880; *New York Medical Record.*

Epithelioma of the Vagina—Occlusion of the Common Iliac Vein—Pyæmia.—Mr. Bellamy (*Med. Times and Gaz.*, 1880, p. 510) had under his care a woman of 58, who, following a strain, had a swelling on the left side of the vulva and in the groin, with a watery discharge from the vagina. This discharge continued, and in a week or two was of a dirty-white color. About a week after the accident the left leg began to swell, at first the ankle, and afterwards as far up as the thigh. The whole lower limb then became of a dusky-red color, and was very painful, the pain being of a throbbing, tingling character. She was able to go about a little for six weeks, but after that was confined to bed. She did not improve, and, as her general health was suffering, she applied for admission to the hospital on April 19, 1880.

On admission, the left leg was much swollen and brawny to the feel. There was considerable œdema, but no special hardness over any of the veins. The surface of the skin was not hot, nor was there any undue tenderness on pressure. There was some discharge of a dirty-green fluid from the vagina. Some obstruction was felt in the rectum on attempting to pass fæces. On examination per vaginam, a nodulated tumor was found involving the whole of the left wall; its surface was ulcerated and discharged thin and very offensive pus. The left labium majus was affected by a nodulated growth, also ulcerated on the surface. The rectum was apparently implicated in the growth. No examination could be made, however, on account of the pain caused. Hot fomentations were applied to the leg, with some relief to the pain and tension, and local applications were ordered for the vagina. No special alteration occurred in the patient's condition for about six weeks.

On June 3 the discharge became more profuse and offensive, and on the evening of June 6 the patient had a severe rigor; the temperature went up to 103°, and, later, to 104.6°. The patient complained of feeling weak, and was extremely depressed; there was slight pain and tenderness in the hypogastric region, and the discharge from the vagina was profuse and somewhat bloody.

On June 8 a red blush appeared on the abdomen, and she complained of pain there. The left foot was swollen and erysipelatous-looking, and, later, fluctuation was found about the ankle-joint.

The patient died June 10. At the post-mortem examination the posterior wall of the vagina and the lower end of the rectum were found to be the seat of an ulcerating epitheliomatous mass. The lymphatic glands of the pelvis were enlarged, and those on the left side so much so that they pressed on the common iliac vein, and so had given rise to the symptoms in the left leg.

NITRO-GLYCERIN IN ACUTE AND CHRONIC BRIGHT'S DISEASE, AND IN THE VASCULAR TENSION OF THE AGED.—Dr. A. W. Mayo Robson (*Brit. Med. Jour.*, 1880, vol. ii. p. 803) has given nitro-glycerin in these cases with great benefit. A man of 56, with puffy eyelids and œdematous legs, a pulse tense and corded, the heart greatly hypertrophied, and breathing labored and difficult at times, was given a one-per-cent. solution of nitro-glycerin in one-minim doses every half-hour till its physiological effects were produced. It relieved the asthmatic symptoms so effectually that the patient would never afterwards be without it. After taking the medicine in three-minim doses thrice daily for a week, the urine, of which only a pint and a half daily, of specific gravity 1008, and very albuminous, had been passed, was now voided to the amount of three pints, specific gravity 1012, and almost free from albumen. This patient continued to take the medicine for some months, with great amelioration of the symptoms.

Dr. Robson mentions another similar case, in which the relief gained was equally striking. In the case of a woman of 52, who had had one slight apoplectic seizure and was threatened with another, and where the pulse was hard and corded and all her vessels indicated increase of tension, nitro-glycerin was administered in one-minim doses thrice daily, with the result of removing entirely all symptoms of dizziness, etc. In the subsequent history of this patient, a dose of the remedy has been taken whenever dizziness has begun to come on, with the result of relieving the symptoms, and, as may be supposed, of averting for the time a threatened attack of apoplexy.

A case of angina, or of anginaform attacks, appeared to be cured by the use of the nitro-glycerin. Other interesting cases are detailed by Dr. Robson, in which patients suffering an attack of acute nephritis were quickly relieved and cured.

Dr. Robson says, in conclusion, that whether the vascular tension which is the symptom treated be due to chronic kidney-mischief or to arterial fibrosis, this condition is unquestionably relieved by nitro-glycerin, and with the diminution of pressure, in his experience, improvement inevitably follows, though in some cases it may be only temporary.

CONTINUED ELECTRO-GALVANIC CURRENT IN AMENORRHŒA.—Dr. R. R. Good (*Med. Times and Gaz.*, 1880, p. 562), in a case of cervico-brachial neuralgia, applied the electro-galvanic current not only to the affected parts, but to the nerve-centres, the upper part of the spine, and the superior cervical ganglion. When, after three months of this treatment, he was able to discharge the patient cured of her neuralgia, he found that she was also cured of a stubborn amenorrhœa which had resisted every internal remedy. As the poles had not been applied to the pelvic viscera, Dr. Good was loath to attribute any peculiar virtue to the electricity thus applied; but further experience now justifies him in asserting the high value of this remedy.

The continued current can find its application only when the affection is due to an inertia of the utero-ovarian apparatus, to a disturbance in the circulation, or to defective nutrition. To resort to galvanism when the evil has its origin in a mechanical obstruction would, of course, be useless. From five to thirty-seven days were required to effect a cure in Dr. Good's cases. The descending current was employed, with twenty to thirty elements for the upper part of the spine, the lumbar and ovarian regions, and from six to ten elements for the sympathetic nerve, applied along the inner border of the sterno-cleido-mastoid muscle.

MISCELLANY.

On the Administration of Medicines in Drop Doses.—J. B. Moore (*Druggists' Circular*, February, 1881) says that medicines should rarely be prescribed in drop doses when it can be avoided, and more especially if the remedy be of a potent, poisonous, or corrosive nature, as it is often very hard to adjust the dose with any degree of accuracy, owing to the difficulty many persons experience in dropping a liquid, and the uncertainty of drop quantities. It often happens, in dropping a medicine from a bottle a little too full or with a badly-formed lip, that the most steady and practised hand can with difficulty drop a dose even with a near approach to accuracy. A few drops too many will sometimes flow out before they can be checked, and the medicine then has to be returned to the bottle and the process repeated again, perhaps with the same result, and to the utter disgust of the person to whom the unpleasant task is delegated. To the nervous and care-worn attendants who are so frequently found in the sick-chamber, the task of dropping medicines becomes doubly irksome and annoying, and especially when it has to be done, as in cases of lingering illnesses, day and night, sometimes for weeks at a time. Besides, it is sometimes impossible, no matter with how much care and judgment the dropping is performed, to prevent the number of the prescription and the directions on the label from becoming defaced, if not entirely obliterated, as is often the case, and the outside of the bottle from becoming stained and bedaubed with the liquid, and especially if it be any of the stronger acids or any of the iron preparations. And the trouble does not always end here, for the hands are liable to be stained, and the clothing, the furniture, or any damageable article that the medicine may come in contact with may be ruined or soiled. Furthermore, medicines which are prescribed in drops are usually very concentrated and powerful, and are often of a very corrosive nature, and therefore the more dangerous to keep about the house and in the sick-room.

There are cases, however, where it is desirable and even necessary for the physician to prescribe his remedies in as compact and as concentrated a form as possible. For instance, when the patient contemplates travelling from home, or when his occupation is of a migratory character, in such cases he may desire to carry the medicine in the pocket or travelling-bag.

Almost all corrosive, pungent, poisonous, and concentrated liquid medicines require to be diluted by the patient at the time of taking, which is often very inconvenient and troublesome; whereas if this were done by the pharmaceutist it would at once not only strip the medicine to a great extent of its noxious or dangerous properties, but would also exempt the patient or attendant from a very unpleasant task; then, if the medicine should happen to be taken by mistake, or innocently by children, a large quantity will perhaps have to be swallowed to produce fatal, or even dangerous, consequences. Many cases of injury and poisoning have followed the taking of very active and concentrated medicine by mistake which has been brought into the family on the prescription of a physician. Many medicines, like carbolic acid, liquor potassæ, and the various mineral acids, etc., are noxious chiefly in virtue of their corrosive nature, and when they are diluted are comparatively harmless and safe to keep in the household.

Besides, many of the poisonous and highly concentrated remedies which are generally prescribed in drop doses are often nauseous to take when simply diluted with water or sugar and water, as they usually are by the patient or nurse; whereas if the physician would prescribe these remedies in combination with simple elixir, syrup of orange, Curaçoa cordial, compound tincture of cardamom and syrup, lemon syrup, etc., or even in mixture with any of the medicated waters and a little syrup, they would form very palatable and safe remedies. In such combination the medicinal ingredients may be so adjusted in the vehicle as to make the dose of the mixture a teaspoonful, two teaspoonfuls, or a tablespoonful, as the physician may desire.

When precision in dose is very necessary or desirable, even the spoonful dose is also rather uncertain and inaccurate, owing to the irregular size and variable capacity of the various kinds of spoons. The dessert-spoon of all others is perhaps the most objectionable and uncertain, and it is best for the physician to direct the dose of all active medicines to be taken in the dose of two teaspoonfuls instead of the dessert-spoonful. In fact, many persons can hardly recognize the difference between the tablespoon and the dessert-spoon, and often mistake one for the other. I have known this to be done frequently in taking medicine.

The graduated tumbler or medicine-glass is perhaps the most accurate and reliable means of measurement of medicinal doses that we have for domestic use; and I think that it would be well for physicians, in all lingering and chronic illnesses especially, to request their patients to procure one of these glasses, as they are certainly a very useful adjunct to the sick-chamber, and cost but a trifle.

Physicians, I have no doubt, often prescribe medicines in the form of drop doses from the force of habit, without ever thinking of the inaccuracy of that mode of administration, or of the inconvenience that medicine given in that form is likely to subject their patient to, or without even for a moment taking into consideration the real danger of sending into

the household such dangerous medicines as are often prescribed in that form.

ENGLISH PRESCRIPTIONS.—The following bills are now before the Legislature of this State:

Whereas, Grievous errors and mistakes have been made by druggists and others in the compounding of the prescriptions of physicians by reason of the same being heretofore written in the Latin tongue and in abbreviations thereof, as well as the quantities or proportions of the drugs or medicines being designated therein by figures or symbols in a mode not readily understood by the bulk of the people, whereby undue advantage and a mystification of the patients may be taken by unscrupulous doctors, druggists, and persons who prescribe or compound medicines for the sick and poor, and it being desirable to simplify the practice of medicine and to enable the public generally to better comprehend the names and nature of such drugs; therefore,

Section 1. *Be it enacted*, etc., That physicians and all other persons engaged in prescribing medicines or drugs for the sick shall write the names, quantities, and designations of the same plainly in the English language and without abbreviations; and a copy of such recipe or medicines so compounded by druggists, herbists, or any other persons shall be labelled or written on the outside of the bottles, vials, or packages containing the same.

Section 2. That any person violating the provisions of this act shall be guilty of a misdemeanor, and, on conviction before a magistrate, alderman, or justice of the peace of the county where such offence may be committed, shall be subject to a fine of twenty dollars for each offence, together with costs, and in default of payment to an imprisonment of not less than ten days or more than twenty days, at the discretion of the court.

Section 3. This act shall take effect immediately.

Whereas, Serious mistakes and confusion in the sale and compounding of medicines for the sick have occurred by druggists and others by reason of the names thereof being written or printed in the Latin tongue; therefore,

Section 1. *Be it enacted*, etc., That all druggists, vendors, or compounders of drugs, medicines, or herbs for the use of the sick are hereby required to label or print the names thereof conspicuously on the outside of the bottles, pots, or packages containing the same, in the English language, and without abbreviations.

Section 2. That any person violating the provisions of this act shall be guilty of a misdemeanor, and, on conviction before a magistrate, alderman, or justice of the peace of the county where such offence may be committed, shall be subject to a fine of ten dollars for each offence, together with costs, and in default of payment to an imprisonment of not less than ten days or more than thirty days, at the discretion of the court.

Section 3. This act shall take effect immediately.

HEBRA'S SUCCESSOR.—The successor of Hebra is Professor Kaposi, who is well known to the profession by his various contributions to the literature of dermatology. A person of quick, nervous temperament, he combines a vast knowledge of his subject with the qualities of a brilliant lecturer and a good teacher. His class numbers more than that of any other teacher in his department.—*Cor. Cincinnati Lancet and Clinic.*

SCIENCE FOR THE YOUNG.—In a small manual for use in Manchester (England) schools we find the following, the standard being intended for children of eleven years, of the poorer classes:

"Man is described by the zoölogist as standing at the head of the animal kingdom. He is described as forming the only species in the order Bimana (two-handed animals), of the class Mammalia (suck-giving animals), of the sub-kingdom Vertebrata (backboned animals). He is further described as breathing atmospheric air by means of lungs; as possessing warm red blood, driven into circulation through his body by the action of a double heart, possessing two ventricles and two auricles; as producing living young, and nurturing them by means of milk secreted by the mammary glands; his skin more or less covered with hairs and scales; as possessing two hands and two feet, each five-fingered, the nails at their extremities flat and broad; and as possessing all his teeth even and close to one another, and his molar teeth equally enamelled."

"This is pretty well," says the *Saturday Review;* "and we only hope that the eleven-year-olds will not be led by the metaphorical expression at the opening to conceive the idea of a groom standing at the head of a horse named Kingdom, and that no awkward mistakes will arise from the use of the masculine in describing the process of nurture. Youth is prone to such little errors when its brains are overdriven."

In the next standard the author explains scientifically the things of common life. Youths of twelve are quite ignorant of what jumping means. He tells them, "Jumping or leaping is effected (1) by the sudden contraction of the muscles of the calf, by which the heels are suddenly raised and the body jerked off the ground; (2) by the simultaneous contraction of muscles which bend the thigh on the pelvis; (3) by the sudden extension of the legs by the contraction of the extensor muscles, this movement following immediately on the two movements first described."

Obviously this lucid explanation will be of little use unless (as an instructor of youth who anticipated the method observed) "he goes

and does it." The joy of intelligent youth when for the first time it consciously contracts the muscles of its pelvis may possibly be a consolation for the trouble of learning. A young philosopher who can define himself as a person who nurtures his young, etc., and who knows that he jumps by contracting the muscles of his pelvis, is obviously ready for instruction in higher things still.

To Remove Fish-Bones. — Fish-bones lodging in the pharynx are rendered flexible and are finally broken up by a mixture of hydrochloric acid (four parts) or nitric acid (one part to two hundred and forty parts of water) used as a gargle, the teeth being protected by oil or lard. So says Professor Voltolini in *Monatsschrift für Ohrenheilkunde.*

Sentimental Chemistry. — A French chemist is said to have condensed the body of his wife into the space of an ordinary seal, and had her highly polished and set in a ring. He made a nice income by betting with lapidaries and others that they could not tell the material of the set in three guesses, and, after pocketing the money, would burst into tears and say, "It is my dear dead wife. I wear her on my finger to keep alive pleasant remembrances of her."

Anecdote of Thierry de Hery.—One day, while this once-famous syphilographer was sauntering through the crypts of St. Denis, paying little attention to the various royal tombs about him, he suddenly precipitated himself before an effigy and began to pray. The verger, who was standing near by, called out to him, "You mistake, sir: that is not a saint's tomb, but that of our late king, Charles VIII." "Simpleton," replied De Hery, "learn that the good king Charles VIII. is more than a saint to me, as he imported the pox from Italy, and has been my benefactor to the amount of thirty thousand pounds a year."—*Canada Lancet.*

Compound Elixir of Chloroform.—Dr. W. F. McNutt, in the *Western Lancet* for August, 1880, recommends the following formula as a substitute for chlorodyne:

℞ Muriate of morphia, gr. ss;
Hydrate of chloral, ʒss;
Chloroform, ʒss;
Tinct. of cannabis indica, ♏xx;
Tinct. of capsicum, ♏xx;
Hydrocyanic acid, dil., ♏xx;
Essence of peppermint, ♏x;
Comp. syrup of sarsaparilla, ʒj.

Mix. Dose, one drachm.

This he has named "Elixir Chloroformi Compositus."

Practical Physiology.—An old lady who has several unmarried daughters feeds them on fish diet, because it is rich in phosphorus and phosphorus is the essential thing in making matches.—*Students' Journal.*

Obituary. — The *Obstetrical Journal of Great Britain and Ireland* terminated its existence at the end of last year.

Hoff's Malt Extract is a substance midway between an ordinary malt extract and a strong ale. Its effect upon the digestion of starch is said to be marked. In a series of experiments, Dr. J. J. Coleman, of Glasgow, found that Burton ale dissolved five per cent. of the starch; London porter, forty per cent.; Wrexham ale, twenty-six per cent.; the genuine Hoff's Malt Extract, sixty per cent.

The Taste of Chloral, which to many persons is excessively disagreeable, may, it is said, be disguised by administering it in syrup of gooseberries, with the addition of a drop of chloroform to each grain of chloral.

Fluid Extracts of Digitalis and Colchicum.—Dr. E. R. Squibb says that these are more eligible preparations than the tinctures. They are eight times as strong, and cost only half as much.

Nearly two million pounds of horse-flesh are said to have been eaten last year in Paris.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM FEBRUARY 6 TO FEBRUARY 19, 1881.

Baily, E. I., Lieutenant-Colonel and Surgeon.—The leave of absence granted him December 30, 1880, from A. G. O., extended one month. S. O. 35, A. G. O., February 11, 1881.

Gibson, J. R., Major and Surgeon.—To accompany Battery A (Light) and Battery D, Second Artillery, from Fort McHenry, Md., to the United States Barracks, Washington, D.C., for temporary duty thereat. S. O. 26, Department of the East, February 11, 1881.

Lippincott, H., Captain and Assistant-Surgeon.—Upon expiration of present leave of absence, to report in person to Commanding General, Department of the Platte, for assignment to duty. S. O. 34, A. G. O., February 10, 1881.

Elbrey, F. W., Captain and Assistant-Surgeon. — Relieved from duty at Fort Bayard, N.M., and assigned to duty at Fort Union, N.M., relieving Assistant-Surgeon Kane. S. O. 31, Department of the Missouri, February 12, 1881.

Byrne, C. B., Captain and Assistant-Surgeon. — To accompany Battery C, Second Artillery, from Fort Johnston, N.C. (abandoned), to Washington, D.C., and then proceed to Fort Barrancas, Fla., and report to the Commanding Officer of that post, for duty. S. O. 11, Department of the South, February 11, 1881.

Hoff, J. V. R., Captain and Assistant-Surgeon.—To accompany the four batteries of artillery from Fort Monroe, Va., as medical officer, to Washington, D.C. S. O. 27, Department of the East, February 11, 1881.

Finley, J. A., Captain and Assistant-Surgeon.—To accompany the battalion Third Artillery from New York Harbor, as medical officer, to the United States Barracks, Washington, D.C. S. O. 27, Department of the East, February 11, 1881.

Reed, W., Captain and Assistant-Surgeon. — To accompany Battery I, Second Artillery, from Fort Ontario, N.Y. (abandoned), to Fort McHenry, Md., and then report by letter to these Headquarters for further orders. S. O. 25, Department of the East, February 9, 1881.

Gardiner, J. De B. W., Captain and Assistant-Surgeon.—Relieved from duty in Department of Arizona, to proceed to Baltimore, Md., and, on arrival, report by letter to the Surgeon-General. S. O. 34, c. s., A. G. O.

Kane, J. J., First-Lieutenant and Assistant-Surgeon. —When relieved by Assistant-Surgeon Elbrey, to proceed to and report for duty at Fort Bayard, N.M. S. O. 31, c. s., Department of Missouri.

PHILADELPHIA MEDICAL TIMES.

PHILADELPHIA, MARCH 12, 1881.

ORIGINAL LECTURES.

ON BLOOD-VESSELS.

A Lecture delivered at the Jefferson Medical College

BY W. S. FORBES, M.D.,
Demonstrator of Anatomy.

GENTLEMEN,—The blood is conveyed through the body by branched membranous tubes named blood-vessels. It is driven along these channels by the action of the heart, which is placed in the centre of the sanguiferous system.

The blood-vessels are divided into three distinct sets: one set, named *arteries*, conduct the blood out from the heart and distribute it to the different regions of the body; another set, named *veins*, bring it back to the heart; whilst the third set, named the *capillary vessels*, or *the capillaries*, are placed between the arteries and the veins and connect them together, without being very definitely marked off from either arteries or veins, thereby allowing the blood to pass through arteries, capillaries, and veins successively in a continuous tubular system. The heart is a hollow, conical, muscular organ, with a membranous investment and lining. Its average weight is about ten ounces, its length about five inches, and its breadth about three and a half inches. Its surface exhibits a longitudinal and a transverse groove, which indicate a division of the organ into four parts, named auricles and ventricles. The two auricles are thin-walled cavities, placed at the base of the heart. They are separated by a partition, and are connected with the great venous trunks, the venæ cavæ and the pulmonary veins, through which they receive blood from all parts of the body. They communicate with the ventricle, each by a large aperture, the auriculo-ventricular orifice, which is furnished with a remarkable mechanism of valves, allowing the transmission of the blood from the auricles into the ventricles, but preventing a reverse course. The two ventricles are thick-walled cavities, forming the more massive portion of the heart towards the apex. They are separated by a partition, and are connected with the great arterial trunks, the pulmonary artery and aorta, by which they send the blood to all parts of the body. At the mouth of the aorta and at the mouth of the pulmonary artery a remarkable arrangement of valves in each case prevents the reflux of the blood into the ventricles. The blood is sent out of the left ventricle into the main artery of the body, named the aorta, and passes through the numerous subordinate arteries, which are branches of that great trunk, to the different parts of the body; then, traversing the capillaries, the blood enters the veins, and is returned by the venæ cavæ to the right auricle. In passing through the capillaries the blood changes in color from red to dark blue, and is otherwise altered in quality. It passes from the right auricle to the right ventricle, and it is driven by the contraction of that ventricle along the pulmonary artery and its branches and through the capillary vessels of the lungs, and, having now become red again, it enters the commencing branches of the pulmonary veins, which, ending by four trunks in the left auricle, convey it into that cavity, whence it is discharged into the left ventricle, to be sent again along the aorta and through the system as before.

The blood may thus be considered as moving out from the heart, or from any given point of the sanguiferous system, and returning to the same place again, after performing a circuit in closed membranous tubes; and this motion is what is properly termed the circulation of the blood. The passing of the blood from the left ventricle along the aorta, throughout the body, and back by the venæ cavæ to the right ventricle, is named the *greater* or *systemic circulation*, and its passing through the lungs by the pulmonary artery and pulmonary veins from the right to the left side of the heart is termed the *lesser* or *pulmonary circulation;* but the blood must go through both the greater and the lesser circulation in order to perform a complete circuit, or to return to the point from which it started. The aorta, which conveys the blood to the system at large, is named the sytemic artery, and the venæ cavæ the systemic veins; whilst the two sets of capillary vessels interposed between the arteries and veins, the one in the lungs, the other in the body generally, are respectively termed the pulmonary and the systemic capillaries.

The blood flows in the arteries from trunk to branches, and from larger to

smaller but more numerous tubes: it is the reverse in the veins, except in the case of the vena portæ, a vein which carries the blood to the liver. This advehent vein, though constituted like other veins in the first part of its course, divides on entering the liver into numerous branches, after the manner of an artery, sending its blood through these branches and through the capillary vessels of the liver into efferent hepatic veins, to be by them conducted into the inferior vena cava and then to the heart. The left cavities of the heart, the pulmonary veins, and the aorta, or systemic artery, contain red or florid blood, fit to circulate through the body; on the other hand, the right cavities of the heart, with the venæ cavæ, or systemic veins, and pulmonary artery, contain dark blood, requiring to be transmitted through the lungs for renovation. The red-blooded division of the sanguiferous system, commencing by the capillary vessels of the lungs, ends in the capillary vessels of the body at large; the dark-blooded part commences in the systemic capillary vessels and terminates in those of the lungs. The heart occupies an intermediate position between the origin and termination of each, and the capillary vessels, pulmonary and systemic, connect the dark and red sets of vessels together at their respective extremities. All these vessels serve as continuous channels through which the blood passes from one part of the sanguiferous system to the other, and in which it undergoes its alternate change of color, becoming dark as it traverses the systemic capillary vessels and red again in passing through those of the lungs.

In adult vertebrate animals the essential constituent of the blood-vessels is a tubular system formed of a single layer of flat cells, or of a delicate nucleated membrane, termed cell-membrane by Remak, and the endothelial tube by His. This tube is the least variable part of the vascular walls, and is present alike in the finest blood-vessels, in the largest trunks, and in the dilated portions of the vascular system,—the heart and the several sinuses,—however much the other constituents of the vascular wall may vary. The capillary vessels and the smaller veins are formed of this tube alone, the elementary constituents of which are delicate, flattened, more or less fusiform, or polygonal cells, composed of a nucleus with surrounding protoplasm, and arranged for the most part parallel to the long axis of the vessels. In the heart and arteries, and in most of the veins, this cell-tube is invested by connective tissue and by elastic and muscular elements.

The arteries, commencing in two great trunks, the aorta and the pulmonary artery, undergo division as in the branching of a tree. Their branches mostly come off at acute angles, and are commonly of uniform diameter in each case, but successively diminish after and in consequence of division, and in this manner gradually merge into the capillary system of blood-vessels. As a general rule, the combined area of the branches is greater than that of the vessels from which they emanate, and hence the collective capacity of the arterial system is greatest at the capillary vessels. The same rule applies to the veins. It follows then that the arterial and venous systems may be represented, as regards capacity, by two cones whose apices (truncated) are at the heart, and whose bases are united in the capillary system. The effect of the division of the arteries is to make the blood move more slowly along their branches to the capillary vessels, and the effect of the union of the branches of the veins is to accelerate the speed of the blood as it returns from the capillary vessels to the venous trunks.

When arteries unite they are said to *anastomose* or inosculate. Anastomoses occur in tolerably large arteries, as those of the brain (forming there the so-called circle of Willis) and the mesentery, the hand and the foot. But especially does this running together, or anastomosis, occur in the smaller vessels. Such anastomoses admit of a free communication between the currents of blood, and must tend to promote equability of distribution and of pressure, and to obviate the effects of local interruption.

The arteries are highly elastic, being extensible and retractile both in length and in breadth. During life they are also contractile, being provided with muscular tissue. When cut across, they present, although empty, an open orifice; the veins, on the other hand, collapse, unless when prevented by connection with surrounding rigid parts.

The smaller arteries have thicker walls in comparison with the larger, but the several components of the wall do not participate to an equal extent in producing this increase of thickness. It is chiefly

effected by an augmentation of the muscular tissue, which becomes abundant in proportion to the diminution in the quantity of the elastic and connective tissue. The tissues which form the investing tunics of an artery are arranged in layers, the thickness of which, as well as the order of their succession, undergoes many variations.

In most parts of the body the arteries are enclosed in a sheath formed of connective tissue, and the outer coat of the arteries is connected to the sheath by filaments of the same tissue, but so loosely that, when the vessel is cut across, its ends readily retract some distance within the sheath. The sheath often encloses other parts along with the artery, as in the case of the sheath enveloping the carotid artery, which also includes the internal jugular vein and pneumogastric nerve. Some arteries have no sheaths, as, for example, those which are situated within the cavity of the cranium. Independently of this sheath, arteries have been usually described as formed of three coats, named, from their relative position, external, middle, and internal, and this nomenclature correctly applies to the structure of the arteries so far as it is discernible by the naked eye. On examination with the microscope, however, some of the coats of these arteries are found to consist of six distinct strata. Proceeding from without to the cavity of the tube within, we have the following:

1. The *tunica adventitia.* This coat is composed mainly of fine and closely-woven bundles of white connective tissue. These bundles of white connective tissue chiefly run diagonally or obliquely round the vessel, and their interlacement becomes much more open and lax towards the surface of the artery, where they connect the vessel with its sheath. This coat is the one in which the nutrient vessels (arteries and veins, the *vasa vasorum*) form a capillary net-work from which a few penetrate as far as the muscular coat, but no farther. It is the coat through the more open portion of which the surgeon's aneurismal needle passes in placing a ligature around an artery. Its proportionate thickness is greater in small than in large arteries. It has some longitudinally disposed elastic fibres running between the bundles.

2. The *external elastic coat.* This coat exists as an independent membrane in the smaller and medium-sized arteries, with but few exceptions. Generally speaking, this membrane is formed by a net-work of fine elastic fibres, which is sharply defined internally towards the muscular layer, but which externally joins the elastic fibres of the tunica adventitia.

3. The *muscular coat.* This coat consists of non-striated muscular tissue, disposed circularly round the vessel, in fine bundles, and consequently tearing off in a circular direction, although the individual bundles do not form complete rings. The considerable thickness of the walls of the larger arteries is due chiefly to this coat; and in the smaller arteries it increases in thickness in comparison with the calibre of the vessel. Fine elastic fibres are found mixed with the muscular bundles, and, here and there uniting, form elastic laminæ which are arranged at nearly regular intervals and constitute septa dividing the muscular tunic into numerous layers. The elastic fibres are accompanied by white connective tissue in small quantity, the proportion of which increases with the size of the artery. In the smaller arteries the muscular coat loses its elastic fibre and the muscle-cells are larger and are in closer proximity with one another; accordingly, we find the vital contractility of these arteries increases and becomes more conspicuous. The transition of a capillary tube into an arterial tube commences with the appearance of scattered transversely-disposed fusiform muscle cells immediately external to the endothelial tube and between it and the tunica adventitia. These cells, at first large and scattered and in a single layer, increase in number and become superimposed upon each other. The aorta and pulmonary artery, however, immediately above the attachment of the semilunar valves, are destitute of muscles.

4. The *internal elastic coat.* This coat consists of several layers of longitudinal net-works of elastic fibres of different degrees of closeness. They take on a membranous character, and form the *perforated* or *fenestrated* membrane of Henle. When small shreds of it are stripped off, they have a remarkable tendency to curl in at their upper and lower borders. The *fenestræ* are round-oval or irregularly-shaped apertures of different sizes.

5. The *internal longitudinal fibre coat.* This is the subepithelial coat. It occupies a position between the internal elastic coat and the most internal or endothe-

lial coat of the artery. It is most constant in large arteries. It is said to be the membrane in which cell-proliferation is most apt to occur, and consequently is to be looked upon as of considerable pathological importance. It is composed of a homogeneous connective tissue, with a large number of branched corpuscles lying in the cell-spaces of the tissue. This membrane in young persons is indistinctly granular, but externally it becomes more distinctly fibrous after it has attained a certain thickness. The greater part of it is easily destroyed by the action of potash.

After what has been said, it is obvious that, whilst a description can be given which shall be applicable to individual arteries and to groups of arteries, no general statement can be given that is appropriate to the entire arterial system. There is, in fact, a certain antagonism between the elastic element of the tunica adventitia and that of the circular muscular layer. There also exists a certain antagonism between the circular muscular layer and its elastic elements. If in any vessel the circular muscular layer predominates, the elastic fibres diminish and recede towards the tunica adventitia. It is in the tunica adventitia of both arteries and veins that we find the vasa vasorum or nutrient vessels. These little nutrient arteries are derived from branches which arise from the artery or a neighboring artery at some distance from the point where they are ultimately distributed, and divide into smaller branches within the sheath and upon the surface of the vessel before entering its coats: they penetrate the middle coat in a circular direction, but are not found in the internal coat. Minute venules return the blood from these nutrient arteries, which, however, they do not closely accompany, and discharge their contents into the vein or pair of veins which usually run alongside of the artery. Lymphatics are present in the outer coat.

While the coats of the arteries when in a healthy condition are insensible, nevertheless, with the exception of the capillary vessels, the presence of nerves has been demonstrated in all blood-vessels, even in the tunica adventitia of the non-muscular veins of the pia mater. These nerves come chiefly from the sympathetic, but also from the cerebro-spinal system. They are distributed to the coats of arteries probably for governing their contractile movements. They form plexuses round the larger arteries, and run along the smaller branches in the form of fine bundles of fibres, which here and there twist round the vessel, and single nerve-fibres have been seen closely accompanying minute arteries. The fine branches penetrate to the middle coat of the artery, in which they are chiefly distributed. These lay aside their medullary sheath and form a plexus of pale fibres, the finest of which are without nuclei. Ganglion-cells occur in the course of some of the afferent nerve-fibres and in the coarser plexuses.

6. The *cell membrane*, or *endothelial tube* of Remak. This coat is the least variable part of the vascular walls. However much the other constituents of the walls of the entire vascular system may vary, this tube is present alike in the finest capillary vessels, in the largest trunks, and in the most dilated portions of the vascular system, the heart and sinuses and veins. The capillaries and smaller veins are formed of this tube alone, the elementary constituents of which are delicate, flattened, more or less fusiform, or polygonal cells, composed of a nucleus with surrounding protoplasm, and arranged for the most part parallel to the long axis of the vessel. The form of the cells lining the capillaries varies to a considerable extent. As a general rule, it is different in vessels of different calibre. Small capillaries present cells that are more fusiform in shape; larger capillaries, cells that are polygonal. After treatment with nitrate of silver the cells appear bounded by sinuous outlines, that are often lobed or dentated, which correspond to the dentations of adjoining cells. They are often destitute of nuclei. The finest capillaries consist only of a tube composed of cells or of a cylindrical layer of protoplasm which has assumed a tubular form. As the capillaries become larger, a delicate tunica adventitia is superadded, which in the hyaloid membrane of the frog is formed of a delicate net-work of fine fibrils composed of the processes of stellate cells lying directly upon the vascular wall. Each of these cells consists of a large elongated nucleus invested by an extremely delicate layer of protoplasm. The number of cells seen on a transverse section of a capillary tube is, with few exceptions, dependent less on their size than on their form, because the size of the cells in the capillaries corresponds with the calibre of the vessels. In the simplest examples a

fusiform spiral cell presents itself, the lateral surfaces of which are in contact, whilst the extremities occupy the spaces between the ends of the adjoining cells. The capillary wall is contractile both in young and in adult animals. This contraction may occur to such an extent that not even a single file of blood-corpuscles can traverse them. Small loop-like projections have been observed to raise themselves from the wall of the capillaries of tadpoles and of the nictitating membrane of frogs, and again become retracted. It is possible that by means of such contractions the corpuscles of the blood may be pressed into the capillary wall and ultimately perforate it.

The *Veins.*—Veins differ from arteries in possessing thinner walls, less elastic and muscular tissue, and for the most part a stronger tunica adventitia. They collapse when they are cut across or when they are emptied. But, notwithstanding their thinness, the veins possess considerable strength: they are stronger, according to some authorities, than arteries of the same calibre. The veins are ramified throughout the body like the arteries, but there are some differences in their proportionate number and size, as well as in their arrangement. In most regions and organs of the body the veins are more numerous than the arteries, so that the venous system is altogether more capacious than the arterial; but the proportionate capacity of the two cannot be assigned with exactness. The pulmonary veins form an exception to this rule, for they do not exceed in capacity the pulmonary arteries, these arteries conveying venous blood from the heart to the lungs, and these veins bringing arterial blood back from the lungs to the heart to be propelled by the left ventricle to every portion of the body. The veins generally are arranged in a superficial and a deep set, and as a general thing the superficial veins have thicker coats than the deep, and the veins of the lower extremities than those of the upper. The large arteries have usually one accompanying vein, and the medium-sized and smaller arteries two, named venæ comites vel satellites arteriarum. But the veins within the skull and spinal canal, the hepatic veins, and the most considerable of those belonging to the bones, run apart from the arteries.

While all the veins are not alike in structure, yet in most of them of tolerable size we discover the same constituent tissues that are found in the coats of the arteries, though developed to a much less extent. Beginning from without and proceeding inwards, we find—

1. The *tunica adventitia*, which is distinguished from that of the arteries by its greater thickness and the very small amount of elastic fibres it contains, and by the presence of non-striated muscular fibres placed longitudinally, which are well marked in the whole extent of the abdominal cava and in the trunks of the hepatic veins and the vena portæ.

The longitudinal elastic fibre, which in arteries of middle size is developed into a distinct membrane, named the external elastic coat, in the veins exists to but a very limited degree and never forms a distinct coat.

2. The *muscular* coat in the veins is much thinner than in the arteries, and has a much larger admixture of white connective tissue. In general, the fibres are both longitudinal and circular, the one set alternating with the other in layers. In accordance with the arrangement of the muscular tissue, the veins may be divided into four groups, namely,—

Veins with longitudinal muscles, as those of the pregnant uterus.

Veins with an internal layer of circularly- and an external layer of longitudinally-arranged muscular fibres, as in the vena cava inferior, the vena azygos, and the portal, internal spermatic, renal, and axillary veins.

Veins possessing an internal and an external longitudinal and a middle transverse layer of muscular fibres: among these are the iliac, crural, and popliteal veins, the branches of the mesenteric veins, and the umbilical veins.

Veins having the circular muscular fibre, such as the veins of the upper extremity, the small veins of the neck, the internal mammary vein, and the veins in the substance of the lungs.

3. The *internal elastic* coat. This coat never acquires the size and strength it exhibits in the arteries, and usually appears as a delicate and rather loose net-work of fibres, which for the most part run in a longitudinal direction, and but rarely, as in the larger venous trunks, undergo development into a fenestrated elastic coat as in arteries. In the iliac and crural veins this coat appears in some places to be split

into two laminæ, which intercommunicate with each other by fine elastic fibrils.

4. The *internal longitudinal fibre* coat is placed, as in arteries, between the internal elastic membrane and the endothelial tube. But it is developed to a much less extent than in arteries. In some veins it is almost wholly absent, as in those of the neck, the axillary vein, the vena cava, the mesenteric and portal veins, the vena azygos, and the branches of the pulmonary vein. The thickness of the layer by no means corresponds with the size of the vessel. Thus, it is absent in the vena cava inferior, reappearing in the iliac vein, and increasing gradually in strength until the popliteal is reached, when it attains its greatest thickness. At this part the membrane often forms thickenings which appear even to the naked eye as small elevations and transverse rugæ. On tracing it farther towards the periphery, its thickness will be found to undergo gradual diminution. The structure of this coat is essentially similar to that of the same layer in the arteries.

5. The endothelial lining membrane or tube consists of cells which when compared with the corresponding cells in arteries present a more polygonal and less distinctly fusiform shape, and are consequently both shorter and broader. Their size varies in different regions.

Cavernous Vessels, Vascular Plexuses.

Cavernous vessels result from the unravelling of the vascular wall, which becomes converted into a spongy tissue. The primary vascular wall becomes teased out into thin trabeculæ and plates, varying in thickness, which are sometimes formed of simple cellular threads and sometimes of all the tissues entering into the composition of the vascular wall. Structures of this kind are rarely met with in the arteries. The structure of cavernous veins consists in some instances of simple trabeculæ of connective tissue, as in the cavernous sinus, whilst in others it contains, in addition to the connective tissue, blood-vessels and muscular bundles running longitudinally and anastomosing with one another, as in the corpora cavernosa of the generative organs. The endothelium of the vessels forms the innermost layer of these blood-cavities.

The cavernous capillaries repeat, on a small scale, the relations of the cavernous veins. In the process of reparation of a wound there originate finer or coarser intercellular blood-paths, destitute of definite walls, which occupy the interspaces of the granulation-cells. Originally they form an intermediary plexus of plasmatic canals which are supplied by the arteries,—the blood issuing through spaces in the unravelled vascular wall and being similarly discharged into the veins. There is no special membrane lining or limiting these blood-passages. A portion of the plasmatic canals subsequently expand into true blood-vessels, the walls of which are formed by the fusion of the cells lining the blood-canals; the greater number, however, disappear altogether. Certain vascular plexuses are closely allied to the cavernous tissues, and indeed not unfrequently, as in the case of the papillæ of the comb of the cock, develop into actual cavernous spaces. Among these vascular plexuses there is one which lies in front of the coccyx in man and deserves special notice from the peculiarities of structure it presents, and to which it owes the names it has received from its discoverer, Luschka, of coccygeal gland and venous gland.

This plexus forms a round or slightly oval pale-red compact body, of at most 2.5 millimetres in diameter, the surface of which is either smooth or slightly tuberculated. Sometimes instead of this single body there may be found from three to six millet-seed-sized masses, connected together by loose connective tissue, and seated on fine branches of the middle sacral artery. According to Luschka, their discoverer, these bodies consist of fibrillar connective tissue.

ORIGINAL COMMUNICATIONS.

THE PHYSIOLOGY OF CLIMATE, SEASON, AND ORDINARY WEATHER-CHANGES.

BY ALEXANDER RATTRAY, M.D.,

San Francisco.

THE discovery of the circulation in 1628 was an important era in the annals of physiology. For not only did it give the true *course* of the blood-current, but a clue to the real *function* of the fluid itself. Till then, the indispensable importance of this to every cell, tissue, organ, and part, to every vital manifestation, and even to life itself, had not been fully realized. Nor had the blood been recognized

as the main element not only in the sanguiferous system but in the entire human economy.

When Malpighi, in 1661, supplied the missing link in Harvey's chain of evidence, by proving the existence of the capillaries, not only was the most important *part* of the circulatory system first pointed out, but the earliest glimpse was given of the pre-eminent *processes* carried on by their agency. Since then the heart has been mainly regarded as a propelling organ for forcing the blood-stream onward; the arteries and veins as little more than tubes for conveying it to and fro between the oxygenating lungs and the craving tissues; while the systemic and pulmonic capillaries, which irrigate the body, are the vessels in, by, or near which the leading vital operations of the human frame are mainly carried on,—an important connection being apparent between the blood-supply and activity of function, so that whatever increases or decreases the one similarly affects the other.

As it performs its tortuous circuit to aid in carrying out the multifarious functions of the body, the all-pervading blood-current from its first establishment until its final cessation pursues its course unvaried, except when influenced, first, by the ever-changing conditions of age, or different external or internal, physical or psychical agents which cause the velocity of the main stream to increase or decrease; or, second, by the local distribution through some of the side-branches becoming augmented or diminished by the ever-varying physiological activity of the organs or parts which they supply.

By none of the material or vital agencies now alluded to, including age, sex, race, idiosyncrasy, diathesis, hereditary predisposition, temperament, mode of life, habits, abode, occupation, diet, work, sleep, mental activity, moral emotion, and such like, are the blood-current and the different organs and functions of the body oftener or more acted on than by *atmospheric variations*, either originating in the air itself, or resulting from a change of locality. So unstable is the meteorology of our globe, and so frequent is travel, that the weather-mutations to which even settled residents are subjected are not only of constant occurrence, but often great and sudden, their important physiological results being unceasing and universal. No race can escape from the influence of one or other of the *climates* that characterize the tropical, temperate, and arctic circles. Nor in any of those zones can any individual elude the phenomena known as the spring, summer, autumn, and winter *seasons*, or evade the still more frequent minor *weather-changes* that mark one day or period from another, or night from day.

Intricate as this complicated physical factor necessarily makes the physiology of atmospheric changes on individuals, still another item must be taken into account if we extend the inquiry to the effect of climate on race. This consists in the difference which exists in the ordinary* and microscopic† anatomy, and doubtless the physiology, of the different races of mankind; no matter whether these are so important as to solve a long-vexed ethnological question by pointing to distinct genetic centres, or so trivial that they may be accounted for by the long-continued action of meteorological, dietetic, and other modifying forces.

Meantime, however, we have only to do with our own, that is, the Caucasian race, born in and therefore fitted for one, namely, the temperate zone, but who often travel to the equatorial belt on the one hand and the arctic circle on the other, and even in their own region encounter marked meteorological contrasts. The vast territory and many varieties of climate and season to which the large and busy population of the United States is exposed make this a subject of especial interest and personal importance.

Few countries possess more varied climatic characteristics than this, which may be said to include those of all three zones, since they range from the arctic of Alaska to the tropical of the Gulf States. Even from the latter to the northern boundary-line they include the isotherms of 40° and 75° Fahr., and thus have a range of 35° average annual temperature (Dove's chart.) The following table shows even more

* Dr. E. H. Shell, of Gainesville, Alabama, states that it has been proved by dissection that the lung of the negro has only two-thirds of the capacity of that of the white man of the same weight and height, thereby suggesting that the respiratory function also differs; that probably every other organ and function shows corresponding anatomical and physiological variations; and that the Mongolian race likewise has its peculiarities.

† This met with its first proof under the microscope of Bakewell (Transactions of Anthropological Society, London, 1871), whose practised eye found an appreciable dissimilarity between the red corpuscles of the Hindoo and the Mohammedan natives of British India sufficient to discriminate them readily almost at a glance. Research may extend this to every tissue and organ, both in these and in other races.

clearly not only the great annual range of American temperatures, but also how much colder are the winter and warmer the summer of some regions than others.

TABLE I.—CLIMATES OF THE UNITED STATES.

Region.	Extremes of Temperature. Highest.	Lowest.	Range.
Eastern or Atlantic States (Boston)*	98° F.	—8° F.	106° F.
Interior or Continental States (St. Paul, Minn.)†	99° "	—39° "	138° "
Upland or Mountain States (Fort Scully, Da.)‡	115° "	—30° "	145° "
Pacific States and Territories (San Francisco, Cal.)§	94° "	+27° "	67° "
Maximum extreme (Fort Scully; St. Paul)	115° "	—39° "	154° "

The equable climate of California forms a marked contrast with the variable ones of the Atlantic, interior, and upland States, where the summer is often tropical in heat and the winter arctic in severity; the daily weather-changes being also comparatively great, as at St. Paul, where the thermometer sometimes varies no less than 40° Fahr. in one day. But even in the Pacific States and Territories the thermometric range is considerable, and varies from the occasionally sub-arctic of Washington Territory to the thermally sub-tropical of Southern California; the winter and summer seasons being also well marked, and the diurnal changes likewise considerable. For example, at Oakland the extreme monthly range is given at 47° Fahr., and the extreme daily range at 38° Fahr.‖

It thus appears that the extreme temperature to which travellers in the United States may be exposed during the year is 154° Fahr.; that the highest to which residents in any one locality may be subjected in a year is 145° Fahr., and the lowest in a year 67° Fahr.; while the local monthly and daily changes from heat to cold, and the reverse, to which all are liable, are often considerable, even in the proverbially fine climate of California, and correspondingly trying to the human frame.

I. THE PHYSIOLOGY OF CLIMATE.

Our knowledge of the vital phenomena induced by change of climate has long been largely hypothetic, because mainly derived either from the effects of season, the artificial atmosphere of heated ovens, the air of mountain-tops, or that met while ballooning; while data were often deduced from experiments, not on man, but on the lower animals.

Obviously, however, the facts most acceptable in human physiology are those made on the *human subject* and in *natural climates;* for human and comparative physiology not unfrequently differ. While dry artificially-heated rooms or ovens are unlike tropical atmospheres, which combine heat, rarefaction, and moisture, so also the air of great altitudes differs from the usual surface-climates of extra-tropical latitudes, which conjoin cold with condensation and moisture. Neither do the abrupt and temporary exposures to heat or cold common in experimentation have many parallels in ordinary life, nor are they likely to induce results similar to the comparatively slow transitions involved in ordinary changes of climate.

Davy's and Becker's experiments on the bodily temperature, Forbes, Watson, and Becker's on the amount of urea and chloride of sodium in the urine, and a few others, have the merit of being made on the human subject and in strictly tropical weather; while as valuable corroborative evidence we have Blagden and Fordyce's investigations on the temperature of animals in the dry air of heated rooms; those of Ludwig and Obermier on the temperature of animals in the moist air of heated ovens; those of Berger and Delaroche on the same subject on man and animals in an artificial temperature; those of Vierordt and Ludwig on the number of respirations in hot weather on animals; those of Vierordt on the quantity of carbonic acid and water excreted by the lungs in animals under artificial heat; those of Prout on man in an artificially-heated atmosphere; those of Blagden on his own pulse in an oven heated to 260° Fahr., etc.

The physiological phenomena which follow marked changes of climate, both in the body generally and in its individual parts, are numerous, varied, and important. Not only the organs and functions of animal life,—namely, the nervous, muscular, and osseous systems,—but also and chiefly those of vegetative life,—namely, the digestive, circulatory, respiratory, secretory, and excretory,—are variously implicated. The more evident effects are so patent that they have been long recognized: for ex-

* Schaff, Smithsonian temperature tables.

§ Dr. H. Gibbons, 1857–77 inclusive.
‖ Dr. I. B. Trembly.

ample, exaggerated or impaired function, especially of the nutritive and eliminatory systems, particularly the skin, liver, lungs, and kidneys; as manifested in the tropics by hyperæmia of the surface, with an increased perspiration, an augmented discharge of bile per rectum, thirst, general lassitude of body and brain, lessened urine, appetite diminished and altered by an increased craving for vegetable and a lessened desire for animal food, and, no doubt, a suitable change in the quantity and quality of the secretions of the entire alimentary canal and its accessory glands.

With the more occult microscopic changes which doubtless take place in the various tissues and organs of the body we have here nothing to do. Our present object is to investigate the *functional* changes, especially those caused by *transitions from temperate to warm climates, and the reverse;* that is, those climatic changes with which the inhabitants of the temperate zone are most familiar, and which are thus of the highest etiological, pathological, hygienic, and therapeutic importance.

Recent research has added considerably to our knowledge of the physiological effects of *climate*,* and we shall presently show that these are identical with those induced by *season*, ordinary *weather-changes*, and other aërial variations, and necessarily of corresponding medical importance.

On proceeding from a temperate to a tropical climate,—for example, from the North to the South Atlantic, a change involving a rise of 29° Fahr. (54° to 83°) aërial temperature,—the following changes occur:

A. A *diminished respiratory function*, as shown—

1. By the ordinary or tidal respiration being less deep, that is, *gentler* to the extent of 1.29 cubic inches, or 8.9 per cent. (14.54 to 13.25 cub. in.).†

2. By the ordinary or tidal respiration being *slower* to the extent of at least 0.9 respiration per minute, or 5.45 per cent. (16.5 to 15.6), and sometimes more. This fact corroborates Vierordt and Ludwig's experiments on animals, whose respirations were lessened in number by artificial heat.‡ This slowing of the respiration conjoined with its lessened quantity proves that *lung-work* is *diminished* in tropical climates to the following extent:

44.22 cubic inches per minute;
2653.20 " " hour;
63676.80 " " day;

or, 36.85 cubic feet of air = a decrease of 18.43 per cent. § And if we take ten ounces of carbon (the mean of three estimates, namely, those of Lavoisier and Seguin, Davy, and Allan and Pepys) as the average amount of carbon thrown off by the lungs in a temperate climate, this reduction of lung-work by 18.43 per cent. gives 8.157 ounces of carbon as the daily pulmonary excretion in the tropics at the above temperature. This corroborates Prout's previous experiment, which showed that carbonic acid is given off in smaller quantity by the human lungs in high temperatures. ‖ Letellier's observations on animals prove the same thing; ¶ while Vierordt's observations show that the same is true of the human subject, less carbonic acid and presumably less water being eliminated when subjected to heat, to the extent of more than two cubic inches of carbonic acid hourly in a difference of 10° Fahr.** Whether this diminution in the excretion of carbon by the lungs is counteracted by a vicariously increased excretion by other carbon-excreting organs,—for example, the skin, liver, and kidneys,—has yet to be determined. It will be subsequently seen, however, that as a rule the liver does not act vicariously under those circumstances, nor probably do the kidneys. The attitude of the skin, however, requires study, and will necessarily be difficult of solution, since the normal amount of carbonic acid excreted by this organ is yet undetermined. The amount excreted by any of these three vicarious organs depends much on the food and exercise. If the former is diminished and also changed according to the dictates of prudence and our "innate chemical instinct" (Aitken) to a more vegetable and less animal diet, while both the brain- and body-tissue-waste are lessened as usual, there is probably no increase in the carbonaceous excretion by these organs, but perhaps a decrease, as with the lungs. A third item must also be taken into account, namely, the lessened amount of air—that

* See a memoir in the "Proceedings of the Royal Society of London," vols. xviii., xx., xxi.; also a translation in the "Archives de Médecine Navale." Paris, 1869 *et seq.*

† Ibid. ‡ Parkes, Practical Hygiene, p. 402.

§ In this calculation the expansion of air and other gases by heat, according to Dalton's and Gay-Lussac's law, has been taken into account.

‖ Hooper's Physician's Vade-Mecum, seventh edition (edited by Drs. Guy and I. Harley), p. 56.

¶ Carpenter's Physiology, p. 594.

** Parkes, Practical Hygiene, p. 402.

is, oxygen—required for the vital processes in the tropics, where, although the tissues decay more rapidly (Carpenter), the lessened amount of brain- and body-work more than counterbalances this, and makes the total quantity of débris to be excreted considerably less. However, when for one reason or another carbon finds its way into the system in the tropics in unusual quantity and the lungs cannot throw it off, then the skin, liver, and kidneys doubtless aid them and excrete it, the former as carbonic acid, and the latter in forms which do not require much oxygen for their formation, namely, as bile and uric acid.

3. By an increased spirometric measurement (vital capacity, pneumatic capacity) of the lungs, which, under a rise of 18° Fahr., increased to the extent of

Lowest = 24 cubic inches = 8 per cent.
Highest = 47 " = 18⅓ "
Average = 31 " = 12¼ "

This average is equivalent to a rise of 1.73 cubic inches of air per degree Fahr., and in the highest amounts to more than one-sixth of the total vital capacity of the lungs. In growing lads (age 14 to 17), in whom the chest is still undeveloped, the average rise in the spirometric capacity amounts to 0.6 cubic inch per degree Fahr.* The figures are doubtless different in the female sex, since their chest is considerably different both in size and in form. Experiments, however, are still wanted to show what this amounts to both in adult and in growing women.

As with latitude, so with altitude in the tropics, there is a rise in the spirometric capacity on going from the colder upper mountain-regions to the warmer atmosphere of the sea-level. This instance involved a thermometric fall of 10° Fahr. (75°–65°) for an elevation of two thousand feet, and gave a spirometric difference of twenty-three cubic inches of air. The reverse necessarily happens on making an ascent.

It has also been proved that this law of an increased spirometric capacity in a warm atmosphere prevails in the negro or Ethiopian as well as in the Anglo-Saxon race, and thus presumably in all varieties of mankind;† also, that the presence of serious disease of the lungs, as catarrh, asthma, phthisis in all three stages, does not prevent the manifestation of this law; the reason of which will presently appear.

It was also shown that the spirometric capacity of the lungs rose and fell in this manner five times successively while changing from zone to zone, thus proving it an unfailing phenomenon; a fact to be subsequently explained.

Another fact forms an important adjunct of this rise in the spirometric capacity; namely, an unappreciably unaltered size of the bony chest, and therefore *no increase in the size of the enclosed lungs.* Nor does the normal growth of the chest which occurs in youth appreciably interfere with or prevent this pneumatic rise and fall, since even the latter is very marked in growing lads.

The only hypothesis by which these phenomena can be accounted for is that the varying spirometric capacity is the result of an alteration in the relative proportion of lung-tissue and lung-blood,—a change in the solids and fluids on the one hand and lung-air on the other, in which the former, the *blood*, is displaced by the latter, or *air*. In other words, it indicates a decrease in the volume of the lung-circulation and a corresponding increase or dilatation of the cells by air. Thus there is only an alteration in the relative proportion of blood and air; the blood-current or lung-vascularity being decreased to the extent of 17.88 fluidounces, the equivalent by bulk of the average spirometric increase of 31 cubic inches (necessarily distributed to other organs, especially the skin), and the air correspondingly increased. The blood, directed mainly to the functionally excited skin, permits the ingress of more air into the pulmonary tubes and cells. Briefly, the lungs in the tropics, unaltered in size, contain less blood actually and relatively, and therefore more air, than in colder latitudes. In changing climates the oscillation in the relative proportion of blood and air follows an inverse ratio,—the one rising, for an obvious reason, as the other falls. Hence it is the rise and fall in the amount of *air* or spirometric capacity, and not in the blood, which corresponds to the rise and fall in the atmospheric temperature. Blood is the displacing and air the displaced agent: the former, drawn surfaceward by the heat of the air and skin, is replaced

* Pacific Medical and Surgical Journal for May, 1880.

† Shell's assertion that the negro lung has only two-thirds of the capacity of that of the white man of the same height and weight must not be forgotten in connection with this. This implies that the spirometric measurement is correspondingly altered.

by an equivalent bulk of air. Under cold the reverse happens.

This tropical increase in the vital capacity of the lungs is no doubt permanent; that is, it lasts as long as the individual remains in a tropical climate. And its rationale is that it is merely one of the sequelæ and manifestations of a greater and more general law of the circulation, to be presently described. This law affects not the lungs only, but every other organ and function in the body; although it is in these alone that it is possible physically to demonstrate its existence and give other proof of the physiological increase or decrease in function common to them and other organs.

Explained thus, this increased spirometric capacity of the lungs in the tropics may be correlated with the previously mentioned facts, namely, *slower* and *gentler* respiration; inasmuch as like them it furnishes another proof of diminished pulmonary circulation and respiratory function. Though apparently conflicting and contradictory, these two phenomena, an increased spirometric capacity and a diminished lung-function, are really allied, and, as reflection will show, merely parts of one and the same physiological law, and to be similarly explained. The correctness of this conclusion is still further corroborated by another fact: that the spirometric increase in the tropics is greatest in those of largest frame, and also at mid-age; that is, in those (*cæteris paribus*) of fullest blood, in whom the derivative effects of climate are most observable. Other three facts, obtained from an unexpected quarter, furnish additional proof of this hypothesis, namely, the diminished excretion of carbonic acid, noticed by Prout;* the diminished post-mortem weight of the lungs in tropical regions, first noticed by Francis, and subsequently by Parkes, who shrewdly supplemented his observation by suggesting that it showed apparently a diminished respiratory function;† and, lastly, the smaller lungs, and, inferentially, the smaller respiratory function, of the negro natives of tropical countries, found by Shell.

Several other new though practically less important facts in pulmonary physiology deserve notice. For example, that in tropical as in temperate latitudes respiration is least frequent in the morning, and gradually increases as the day advances. Also, that the difference between morning and evening respiration is not so great in the tropics as in cold latitudes, where the lungs play a more active part in heat-generation and the elimination of carbon and watery vapor.

Although not yet verified by experiment, the pulmonary exhalation of watery vapor is doubtless diminished to the same extent as the excretion of carbon, namely, by 18.43 per cent. The amount in temperate regions has been reckoned at one-quarter the surplus water of the body, or from six and one-half to thirty-one ounces during the twenty-four hours.‡ By taking twenty ounces as an average, this would make 16.32 ounces for the tropics. But whether this and the 1.843 ounces less carbon, one or both, are or are not excreted by other organs, such as the vicariously acting skin and liver, so as to make the total excretion in the tropics and in temperate regions correspond, has yet to be determined.

B. That changing from a temperate to a tropical climate, even when the increase of temperature is only 27° Fahr. (57° to 84°), affects the circulation, is proved by the radial *pulse* being on an average two and one-half beats slower in the latter. And sphygmographic observation may prove what this suggests,—that the pulse is diminished not only in frequency but also in *force*. In the opinion of Parkes, however, the pulse is perhaps not so full in the tropics, but quicker; though in animals he avers that moderate heat does not quicken the pulse, but great heat does.§ Hooper likewise states that the pulse increases under warmth and diminishes under cold.‖ Further observation is thus wanted to settle this disputed point. At the same time, the derivation of blood from the heart and great vessels of the interior of the body to the surface seems to point to a reduction in the force and frequency both of the heart and pulse. The slower and smaller pulse of the tropics, indicative of a more languid circulation, should be correlated with the diminished respiratory function, thus furnishing another proof of the close physiological connection that exists in the

* Hooper's Physician's Vade-Mecum, p. 56.

§ Practical Hygiene, p. 403.
‖ Hooper's Physician's Vade-Mecum, p. 196.

tropics, as elsewhere, between the respiration and the circulation.

Several minor facts connected with the pulse are interesting. For example, that as in temperate latitudes* so also in the tropics the highest pulse of the day occurs, although by no means invariably, in the morning. Also, that the average morning and evening pulse are lowest in the tropics, the average afternoon pulse, however, being higher in the latter. This is probably due to the solar heat, greatest at that period of the day, and is doubtless physiologically connected with a corresponding rise and fall in the temperature of the body at the same periods.

C. Regarding the bodily temperature (under the tongue), a subject necessarily largely connected with the circulation, respiration, and cutaneous function already criticised, as well as with the ingesta, exercise, and aërial temperature, observation goes far to indicate that on proceeding from a cool to a tropical latitude the bodily temperature shows a gradual though comparatively trivial increase, more or less in accordance with the temperature of the air. Thus, as the atmospheric temperature rose from 57° to 84° Fahr., the bodily heat rose from 98° to 98.3°, then to 98.6°, then to 98.8°, and occasionally even to 100°; the average being 98.836°. This apparently indicates that the blood itself increases slightly in temperature; the tempero-tropical range of bodily temperature being thus about 2°. This corresponds closely with Davy's observations, who gives the rise as from .5° to 1° Fahr.† Eydaux and Brown-Séquard give from 1° to 2¾° and 3° Fahr. These variable figures are explained by the naturalists of the "Bonita," who say that it rises more in some than in others.‡ Blagden and Fordyce's experiments show how much the temperature of the body depends on the cutaneous exhalation. Thus, in the dry air of an oven heated to 260° Fahr. the temperature of the skin rose only 2½°. But when the air of the heated oven is so moist as to hinder evaporation, the bodily temperature rises rapidly, as much, according to Ludwig and Obermier, as 7° or 8°.§ Some observers have averred that there is no rise in the bodily heat; and, as if to compromise, Parkes suggests that the rise is only temporary, and that the bodily heat soon returns to its original standard.‖ The following recent observations, however, on the difference between summer and winter bodily temperatures in California (which necessarily correspond in kind, though not perhaps in degree, with those of hot and cold latitudes) show the decided rise in summer of from ¼° to ¾°, average ½°. This reconfirms Davy's observations for the tropics. And when we remember that the bodily temperature is mainly engendered in or near the capillaries by the oxidation of the effete tissues, especially their carbon, as well as the great development of the cutaneous capillary system and its increased respiratory and perspiratory activity in the tropics, and conjoin these with several facts to be subsequently noticed regarding the cause of the perspiratory function, common sense seems to endorse original observation as to the truth of the pioneer experimentalists' researches.

The regulation of the bodily temperature is no doubt largely under the control of the nervous system. And the thermic centres and nerves by which the bodily heat is regulated are doubtless in close sympathy with the sudorific nerves and centres, which likewise aid in controlling it in warm atmospheres. In ordinary circumstances, even when the temperature of the air rises to 120° Fahr. or more, as in British India, the cold induced by the evaporation of the perspiration suffices to keep the temperature of the skin and body down to the normal standard. Occasionally, however, when the solar heat acts on local spots with its full intensity, the evaporation is not sufficient to keep the temperature down, the blood and tissues are superheated, and morbid action results. A notable example of this is probably to be found in that form of sunstroke in which local coagulation of the albumen or myosin of the blood¶ is the chief pathological result.

Another but a minor fact in tropical physiology is that the bodily temperature is greatest during the afternoon, when the sun is hottest, the air most stagnant and humid, the body and brain most active, and digestion—that is, the addition of heat-producing material—most vigorous. So also it is least in the morning. These

§ Parkes, p. 402.
‖ Ibid., p. 401.
¶ Albumen coagulates at 158° (Carpenter), and myosin begins to coagulate at 113° F. (Kühne).

facts are apparently corroborated and increased in interest by the previously mentioned fact that the tropical pulse is also highest and lowest then.

D. That the liver-work is increased in warm atmospheres is a generally received opinion. But this has not yet been demonstrated. And it appears not improbable that the reverse holds good, and that with the diminished respiratory function and excretion of carbon and watery vapor there is possibly a reduced hepatic secretion also. The evidence on this point, however, is merely circumstantial. Nor, from the nature of the case, is positive information ever likely to be attained, any more than we can accurately determine the quantity secreted in temperate latitudes, itself a still unsettled question. Probably the credit of secreting more bile in the tropics is to be accounted for by the fact that more bile comes away by the bowels. But this by no means proves that the hepatic secretion itself is increased. On the contrary, though more is *excreted*, no more may be *secreted*, but possibly less. In connection with this let the amount and use of the bile be remembered, and also the fact that only a small part of the biliary secretion is *excreted*. The daily amount secreted in temperate latitudes is averaged at one pint, or nine thousand grains; which is equal to nine hundred grains of solids, or nearly five hundred and twenty grains of carbon.* Of this only about twenty grains are voided daily with the fæces. The rest, or five hundred grains,—that is, more than one ounce of carbon,—finds its way into the intestines, to be reabsorbed into the blood, to serve as fuel for the lungs. Now, as less heat-generating pabulum is required for the lungs in the tropics, we may also conclude that less of the bile secreted there is absorbed for this purpose, and that more of it is discharged by the bowels; and, furthermore, that probably the biliary secretion itself is also lessened in quantity to correspond with the diminished requirements of the system. Thus, although the tropical *excretion* of bile, that is, the amount discharged by the bowels, is undoubtedly greater, the primary hepatic secretion is possibly less; the presumed increase being only apparent and deduced from fallible data. In this manner the apparently increased biliousness and tendency to diarrhœa, dysentery, and hepatic ailments in the tropics may be accounted for. The irritative secretion per rectum being normally increased, even the slight congestive chills so apt to occur there from checked perspiration necessarily tend to augment not only the hepatic secretion itself, but also the percentage excreted.

E. It is impossible to separate any consideration of the influence of climate on the kidneys from that on the skin. None of the organs of the body are more seriously affected by great changes of climate than these organs and their secretions. This involves both their ordinary and their vicarious functions, their waste product as well as their water-excreting duties. On going from a temperate to a tropical latitude there is a diminished nephritic secretion to the extent of seventeen and a half per cent. for a rise of 18° Fahr. temperature (63° to 81°).† This diminution involves not only the fluid but also the solid constituents of the urine.‡ Both are due partly to the reduced ingesta, and partly to the vicarious action of other organs, especially the skin and liver; while the decrease in the solids no doubt involves both the urea and the chloride of sodium,§ and also the whole of its ordinary saline and inorganic ingredients. It was also shown that, as in temperate latitudes, so in the tropics the kidneys are still the chief eliminators of water; and that the urine is perhaps not so often or so much diminished in the tropics as is usually believed, and then only when the drink is stinted in quantity; but not when this is increased or decreased to suit the temperature and the augmented or diminished demand for fluid ingesta. After copious imbibition of fluids the perspiration breaks forth copiously and early, showing that it is more the cutaneous than the nephritic secretion which alters and either rises or falls contemporaneously with variations in the amount of drink in the tropics, and meets any additional strain in the water-excreting function; while the reverse holds good in temperate climates. In warm regions the functionally excited and vicariously active skin acts as a safety-valve for the kidneys during stress of function; as the latter do for the former in cold latitudes. In all places the amount of urine depends much on the quantity of the fluid

* Hooper's Physician's Vade-Mecum, p. 59.

† See memoir, Proceedings of Royal Society, vol. xviii. *et seq.*

‡ Ibid.

§ Drs. Forbes, Watson, and Becker, Parkes's Physiological Hygiene, p. 403.

ingesta; whereas the perspiration depends largely on the temperature.

F. Closely related with all these phenomena, but especially with the latter, is the increase in the cutaneous function. Under a rise of 18° Fahr. (63° to 81°) the perspiration increased by no less than 22.15 per cent., thereby causing the skin to rank next to the kidneys as the chief eliminator of surplus water, and to take the place of the lungs, which in the temperate zone is the second-rank but in the tropics only the third-rate water-excretor. The skin, which thus throws off water at the expense of the kidneys and lungs, doubtless acts vicariously also in throwing off the carbon and nitrogen usually excreted by the kidneys and the carbon of the lungs. There can be little doubt that frequent change of climate from temperate to tropical, and the reverse, tends to develop both the ordinary and the safety-valve action not only of these but of all the other organs of the body within moderate bounds.

The relative excretion of water by the four great depurating organs in the tropics, and the difference between this and the proportionate amount in temperate latitudes, is shown by the following table:

TABLE II.—RELATIVE EXCRETION OF FREE FLUID IN TEMPERATE AND TROPICAL LATITUDES.

Organ.	Temperate Zone. (Dalton.)* Free fluid drunk = 76 ounces daily.				Tropics.† Free fluid drunk = 88 ounces daily.				Rise or fall in the tropics.
		Oz.	Proportion.	Per cent.		Oz.	Proportion.	Per cent.	Per cent.
Kidneys	(about)	45.25	4/9	59.54	(about)	37.	4/9	42.04	—17.50
Lungs	(somewhat more than)	20.50	1/4	26.97	(somewhat less than)	19.58	1/4	22.25	— 4.72
Skin	(rather less than)	6.50	1/12	8.55	(about)	27.22	1/3	30.93	+22.38
Bowels	(about)	3.75	1/20	4.93		4.02	1/21	4.78	— .15

Thus, while the kidneys are the chief water-excretors in all climates, the relative importance of these four organs as water-eliminators in the warm and temperate zones is as follows: for the temperate zone the kidneys, lungs, skin, bowels, and for the tropics the kidneys, skin, lungs, and bowels. And while in the tropics the excretion of water by the kidneys diminishes by 17.50 per cent. and by the lungs by 4.72 per cent., that by the skin increases by no less than 22 per cent.

With this increase in the perspiration there is probably an increase in the cutaneous exhalation of carbonic acid, which in temperate latitudes has been estimated by Dalton as ¼ oz. of carbon. Liebig's estimate, however, for the temperate zone is considerably larger, since he found that an adult taking moderate exercise expires daily from the lungs and skin combined an average of 13.9 oz. of carbon. To find that exhaled from the skin alone we must deduct the quantity excreted by the lungs. According to Dalton, this is 10¼ oz., while of three estimates by Lavoisier and Seguin, Davy, and Allan and Pepys, it varied from 6.44 to 11.76 oz., giving a mean of 10 oz. Now, if we deduct even the highest of these estimates, it would give a considerably larger excretion of carbon by the skin in temperate latitudes than given by Dalton. Further observation on this point and on the amount for the tropics is clearly wanted, especially to determine whether the latter compensates for the decrease in the pulmonary, hepatic, and nephritic excretion of carbon as it does for the watery excretion. However, as the carbon-excretion depends mainly on the ingesta and on the amount of mental and bodily exercise, and as the former is usually not only less in quantity but also more vegetable and less animal in accordance with the dictates of prudence, and thus for both reasons less carbonaceous, while the body and brain are usually less active, and thus furnish less tissue-waste, it is probable that the excretion of carbon by the functionally-excited skin in the tropics, though somewhat increased, may not be augmented to the same extent as the excretion of water.

Those functional changes already discussed are not only the most evident but also the most important, inasmuch as they are those which by *their perfect fulfilment bear most on the preservation of health and the prevention or cure of disease, and the*

* Hooper's Physician's Vade-Mecum. Although the free fluid drunk is different in Dalton's experiments and this, the proportionate results are necessarily of the same value.

† This table is slightly altered from that in the memoir to correspond with the above-quoted modified views regarding the excretion of bile.

hygienic or therapeutic methods by which these objects are best attained. How much the blood-current has to do with all of these different physiological phenomena, and how much it likewise is affected during change of climate, season, and weather, will appear presently.

G. But, besides these functional changes in the organs of vegetative life, other important but more tardy and hence less noticeable changes are apt to follow migrations from temperate to tropical climates, or the reverse, in the organs of *animal* life, namely, the nervous, muscular, and osseous tissues. These are not due, like the changes already spoken of, to a diversion in the blood-current, but to changes in the blood itself and the tissues which it nourishes; the early and primary effect on the tissues being chiefly quantitative and physical. In short, it affects their *bulk* only. But when prolonged and great, especially if conjoined with other adverse agencies, then their *composition* becomes affected, and the result is qualitative and chemical. These changes are chiefly manifested by a decrease in the vital energy, weight, strength, and health, with languor of body and brain and a general impairment of the physique. Under a prolonged stay in the tropics even the constitution and temperament become modified, the frame undergoes premature decay, life is shortened, the offspring becomes mentally and physically degenerate, and families ultimately extinct.* The subject is thus hygienically and even socially important.

Individuals occasionally fatten in warm atmospheres, and instead of losing flesh they gain in this as well as in health and strength; while, on the other hand, a corpulent person may decrease considerably in weight, while his health instead of impairing actually improves. In such instances the effect of climate is purely physiological. But such cases are exceptional, and consist mainly in unimportant fluctuations in the amount of adipose tissue. As a rule, however, the issue includes loss in flesh, health, strength, general deterioration of the physique, and after a time an increasing percentage of sickness. Thus the effect, though perhaps healthful at first, unquestionably soon becomes slowly and surely pathological, and predisposes to, even if it does not originate, disease.

Thus, it has been proved that among adults sixty-four per cent. diminished in weight an average of five pounds on going from a temperature of 50° Fahr. to one of 88° Fahr. When another adverse influence, namely, a salt-meat diet, was superadded to that of tropical climate, the percentage who lost weight increased to sixty-five per cent., and the average loss to six pounds. If still another unsanitary influence, namely, moist atmosphere, was added, the rise went up to seventy-six per cent., and the average loss to seven pounds. If still another morbific agent, namely, hard work, was added, the number who lost was ninety-one per cent., and the average loss six and three-quarter pounds. This is clearly a very close approach to the border-land of disease. If to these another morbific agent is added, viz., impure air, the result passes the bounds of health, and actual disease in various forms results.† So that, regarded as a whole, these results when prolonged or excessive, if not actually morbid, predispose at least to asthenic processes. These results will be more clearly shown by the following table:

TABLE III.—TO COMPARE THE EFFECT OF CLIMATE, ETC., ON THE WEIGHT.

Pernicious influences.	Gain or unchanged in weight.		Loss in weight.	
	Per cent.	Average pounds.	Per cent.	Average pounds.
None	90.36	6.3	9.64	2.62
One (tropical climate)	35.30	3.	64.71	5.
Two (tropical climate in *dry* season, and salt meat)	34.78	3.9	65.22	6.39
Two (tropical climate in *wet* season, and salt meat)	23.66	2.8	76.34	7.15
Three (tropical climate, salt meat, and hard work)	8.73	3.66	91.26	6.96

The same thing is observed among boys, who normally ought to grow steadily in weight, breadth, height, and strength, but of whom ninety-seven per cent. lose weight in the tropics or do not increase even on a wholesome diet. In the majority growth is retarded; in some it is stopped, both weight and health being affected. Many increase in height in tropical weather, but not in breadth or weight, and thus shoot vertically, like sickly plants. This is evidently an unnatural mode of development, and the best proof that to send young undeveloped lads, girls, or young recruits,

* Copland's Medical Dictionary.

† See an "Analysis of Ship-Air," Medico-Chirurgical Transactions of London, vol. lvi.

whether soldiers or sailors, to tropical climates, is unwise, and not the best mode to produce strong, healthy, long-lived men and women.

In this change in the weight probably every, or nearly every, tissue in the body is more or less implicated, especially those which compose the great bulk of the frame, the organs of animal life. The blood is doubtless reduced by the excessive elimination of watery fluid. The osseous system, and the thoracic, abdominal, and cephalic viscera, are probably little changed. The fibrous and gelatinous are probably more altered, but it is difficult to separate this from the change in the fatty, muscular, and nervous tissues, the three doubtless most of all affected. Since fat is less needed to keep out cold and to generate heat, muscular action, nervous energy, etc., it is probably first used up, as it is a positive encumbrance, does not play a vital part in the human economy, and does not materially influence health by its removal. Strength is the manifestation of muscle acted on by nervous influence, and, as these diminish *pari passu*, the result is doubtless partly due to reduced energy and diminished weight of the muscular and nervous tissues. To these we must add the more rapid decay or waste of the tissues in warm atmospheres,* and doubtless also an imperfect renewal of tissue from diminished lung-work, that is, oxidation of the blood. On the other hand, the languor and weakness felt in the tropics are doubtless due, first, to loss and relaxation of the muscular element; second, to a similar loss and relaxation of the nervous tissue; third, to suboxidation of the blood, and therefore impaired activity both of the muscular and nervous systems; fourth, to a reduced supply to the muscles and nerves of the vital stimulant the blood, diverted largely from these centres to the cutaneous surface.

When an opposite change of climate is made, namely, from tropical to temperate regions, *physiological changes of an exactly reverse kind follow.* The heat of the surface and quantity of the perspiration return to the old standard; the pulse rises; the pulmonary function, and also the secretions of the kidneys, and probably the liver, increase in a corresponding ratio. It was also proved that the spirometric capacity, and therefore presumably that every one of the above phenomena, *oscillates* each time a change of climate is made, the functions of individual organs rising or falling in tropical regions and again returning to the old standard in colder latitudes, and so on indefinitely.

Again, if an inhabitant of the temperate zone proceeds in an opposite direction, namely, to a cold or arctic climate, the above physiological changes are still more marked. The pulse rises; the respiration is also quickened, and the excretion of carbonic acid and watery vapor by the lungs is increased. The urine increases, and doubtless both the actual secretion of bile and the proportion reabsorbed by the intestines for respiratory purposes. On the other hand, the cutaneous function is diminished. These phenomena increase till the sensation of cold, nature's safeguard, warns to keep the body warm by increasing the food, exercise, clothing, and artificial heat so as to prevent them from going beyond the healthy standard and becoming excessive, that is, pathological.

It follows that these phenomena have a certain healthy *range* and extreme limit both for the tropics and the frigid zone, certain bounds beyond which they cease to be sanitary and become pathological. This doubtless varies somewhat according to age, sex, race, and idiosyncrasy, a fact best illustrated by the pneumatic capacity of the chest in which the individual differences are well marked.† However, the percentages for different organs given in Table I. may be taken as a fair average of the *healthy* limits of increase and decrease; and this range doubtless holds good even when a greater change of climate is made than in this instance (42° to 88° Fahr.), as in British India, where the temperature is not unfrequently 160° Fahr. (Parkes), and arctic or antarctic regions, where the thermometer is not unusually considerably below zero. In extreme tropical heat the perspiration and various appliances used to cool the body usually suffice to prevent hyperæmia of the skin on the one hand and over-depletion of internal organs on the other, and thus maintain a healthy balance. In very cold climates similar objects are attained by clothing, fires, shelter, and food. And thus, however great the change of temperature, the range of function is kept within the above-mentioned healthy bounds.

* Carpenter's Physiology, p. 582.

† Proceedings of the Royal Society, vol. xviii.

It thus appears that during changes of climate the different organs, functions, and even tissues of the body are constantly varying and undergoing an almost ceaseless series of physiological fluctuations, especially marked in the secretions of the four great depurating organs, the liver, skin, kidneys, and lungs. The practical application of aberrations of these furnishes a clue to the *causation, development, and beginnings of many of those diseases, especially congestive and inflammatory ones, that are so common, severe, and often so fatal, both in cold and in warm latitudes.* And, clearly, if changes so manifold and important occur in the different functions of the body by a climatic change of 29° Fahr., *others at least as great are undergone by the inhabitants of the United States* during the greater yearly, monthly, and diurnal ranges of temperature to which even the stay-at-homes, and still more travellers, are subjected.

(To be continued.)

A CASE OF POTT'S DISEASE IN THE ADULT TREATED BY THE PLASTER BANDAGE—RECOVERY.

BY J. F. WALSH, M.D.,

Camden, N.J.

JULY 20, 1878.—Paid my first visit to Mary O. She gave the following history. Two years ago, health commenced to fail; she lost flesh and strength; appetite became very poor; noticed shooting pains in back and legs occasionally. Four months later, sharp, acute pain in right groin, extending to inner side of right thigh. Right leg became very weak and dragged in walking. On rising in the morning from the lying posture, experienced quite violent pain in lower portion of spine. Eight months later, a small lump appeared in right groin. General health gradually grew worse and worse.

I found her in a miserable condition: great anæmia; emaciation; dyspepsia and constipation; palpitation and dyspnœa on slight exertion; pulse weak and rather rapid; tongue covered by a thick, yellowish-white fur; a hectic, feverish state nearly every afternoon.

Examination of abdomen revealed a large tumor occupying the right iliac, about one-half of the hypogastric, and small portions of the right lumbar and epigastric regions. Tense, slightly elastic, dull on percussion. About half an inch above centre of Poupart's ligament, a slight elevation of its surface, where an indistinct sense of fluctuation could be detected. At lower portion of spine a posterior angular curvature, involving the last dorsal and two first lumbar vertebræ, was found. The bodies of these were enlarged and tender.

August 29.—Under the administration of tonics—cod-liver oil, iron, and strychnia—and laxatives, in conjunction with a generous diet, her general condition had now very much improved: hectic disappeared; bowels regular in their action; appetite increased. Abdominal tumor had slowly increased in size, and showed distinct signs of pointing. The elevation above Poupart's ligament more marked; fluctuation could be distinctly felt here, and the skin covering it was slightly discolored. It was aspirated by Dr. W. W. Keen, and thirty fluidounces of thick, laudable pus withdrawn. Operation caused no pain, but was followed by a sense of great relief.

For four days subsequently patient was kept in bed. No untoward symptoms manifested themselves. On second day after there was a slight febrile reaction, temperature going up to 99½°; but this subsided on fourth day. In interim cod-liver oil discontinued, and quinine alone administered. Nourishment light and unstimulating.

September 7.—Sayre's plaster bandage applied by Dr. F. C. Sheppard, assisted by myself. Patient delighted with the support it afforded, and was now too anxious to walk.

September 14.—I aspirated abscess. Twenty-eight fluidounces of pus, of same character as on previous occasion, withdrawn. Slight increase of temperature for the three following days, ranging between 99° and 99½°. Same treatment.

November 12.—Tumor having filled up to some extent, I again aspirated. After drawing off eight fluidounces of pus, the instrument got out of order, and I was obliged to desist, leaving some in the sac. No febrile reaction followed operation.

November 29.—Patient improved very rapidly; in fact, she now appeared to be in perfect health. Took a walk every day, and attended to her household duties. Cod-liver oil and quinine every day since September 14. Bandage having cracked,

a new one applied. Before doing this, abdomen and back examined. Tumor almost entirely disappeared; slight dulness on percussion over a small area above Poupart's ligament; angular curvature not increased; diseased vertebræ but slightly tender to pressure, and evidently consolidating.

December 29.—Patient had all the appearances of being in perfect health; in fact, felt so well that she refused any more medical attendance. Cod-liver oil discontinued.

July 15, 1879.—Met patient by accident. She told me that, feeling perfectly well, she took off the plaster bandage about four months ago, and had suffered no inconvenience in consequence since.

July 30.—Made an examination of abdomen and spine. Clear tympanitic percussion over area of former dulness; no tenderness. Diseased vertebræ well consolidated and entirely free from pain or tenderness; angular curvature slight.

At present writing (February, 1881) she says she feels nearly as well as she did previous to her sickness; occasionally, in damp weather, she experiences sharp, shooting pains in right groin and thigh.

Remarks.—The pointing of the psoas abscess above instead of below Poupart's ligament is peculiar and interesting.

A CASE OF PREMATURE LABOR INDUCED BY THE INGESTION OF A DRACHM OF CROTON OIL —RECOVERY OF THE PATIENT.

BY EDWARD T. REICHERT, M.D.

LATE in the evening, about a week ago, I was called out to see a woman whom I found to be suffering with considerable fever, pain, and with symptoms of inflammatory lesion. She was given a fever and anodyne mixture, to be taken in dessertspoonful doses every two hours until relieved, in connection with which was also prescribed a counter-irritant application, consisting of one part of croton oil to two of olive oil, with directions to rub the painful portion of the chest with it twice or thrice a day. The patient, being in impoverished circumstances, and unable to pay for the prescriptions, was obliged to wait until morning in order to obtain them at the city dispensary: consequently, morphia was given internally, and an extemporaneous counter-irritant used in lieu of the croton oil.

The following morning about twelve o'clock a messenger stated that the woman was decidedly worse, in great suffering, and asking me to come without delay. Having reached the scene of distress, the patient was found to be in a condition of semi-collapse, with a high fever, a rapid, feeble, and irregular pulse, pain in the mouth, throat, and stomach, and great distress in her bowels. On further questioning her, it was found that the first dose had caused violent purging, colic, and nausea, and an acrid, burning sensation in the mouth, fauces, œsophagus, and stomach: the purging was accompanied by tenesmus and burning at the anus. The second dose aggravated this condition, and headache, palpitations, and a condition of great depression ensued. A third dose had the effect of still further increasing the severity of these symptoms, and the purging and colic became violent, and to these symptoms was superadded a new feature, in the appearance of pains resembling those of labor, which grew worse and worse and only ceased when a seven-months' child was born. The birth had taken place before I had arrived, as had also the death of the child, which had lived but a few minutes.

Knowing, of course, the composition of the two mixtures prescribed, and that only one of the two could possibly produce such disastrous results, it at once became evident that through some mistake the patient had been given the wrong mixture; and upon further investigation this was found to be the case, the mistake lying with the attendant, as both bottles were labelled properly, and it therefore must have been due to the most flagrant carelessness. The woman had taken three full dessertspoonfuls of the oil in four hours, containing a full drachm of croton oil.

Stimulants were freely given, opium and bismuth administered every hour, counter-irritation made over the abdomen, liquid diet and absolute quiet enjoined. The abdomen in the region of the bowels remained tender for four or five days, and the stools were quite bloody and mucous for two days, but they gradually became more natural, and at the present writing are quite so. The woman is now feeling pretty well and strong, is using tonics, and to all appearances is well on in her convalescence.

CASE OF PLEURISY.

BY R. B. OKIE, M.D.

O. N., æt. 9 years, female. Had been treated for "gastric irritation," and sent to the country to "get well," by her homœopathic attendant,—this in consequence of an attack of illness towards the last of March, 1880, in which pain in the left side, fever, and difficulty of breathing were the prominent symptoms. Saw the child first July 12, in the evening. She was very much emaciated, pulse about 160, and respiration 54 per minute, temperature high, night-sweats profuse. Found the *left* side perfectly dull from apex

to base, intercostal spaces bulging, absolutely no respiration, and heart (apex-beat) half an inch to left of right nipple. Ordered quinia, digitalis, and alcoholic stimulants. Advised paracentesis thoracis, her father being sent for, and consenting. On the 15th of July drew off, by means of the aspirator, twenty-eight fluidounces of pus, the trocar being introduced one inch below and a little to the left of the angle of the scapula.

The child was greatly relieved, and began to improve. Heart-beat moved under the sternum, and lung partly expanded. The fluid again accumulated, and on August 8 tapped again, in ninth intercostal interspace, under the posterior angle of axilla. By holding the canula with the distal end well down, it was possible to empty the pleura more thoroughly, and forty fluidounces of pus were drawn off. Child so much relieved that she slept all night, and took quite a walk next day. By the 17th, as the effusion was again giving trouble, it was decided to introduce a drainage-tube. This was done by the curved trocar-needle, introduced two spaces above and a little to the front of the seat of the last puncture, and brought out at that point. Being threaded with a piece of perforated drainage-tube, the needle was withdrawn and tube secured. Fifteen fluidounces of pus were drawn, making eighty-three fluidounces in all. About two fluidounces of pus escaped daily at first, but gradually lessened, and October 5 the tube was removed. At present the child is in good health, pulse normal, respiration 28, heart in proper position, chest much flattened, but respiration on that side considerable and improving. A very slight daily oozing, about one-quarter fluidrachm, from the upper puncture, but no accumulation.

Quinia, iron, digitalis, and alcohol freely used. Iodine tinct., one-quarter strength, occasionally injected, and daily washings with a solution of potas. permanganate practised while possible.

Drs. Pleasants, Sargent, and Nancrede saw the case with me from time to time, and their advice and assistance I fully appreciate.

BERWYN, PA.

TRANSLATIONS.

VAGINAL CHANCRES.—Dr. M. P. Binet (*La France Méd.*, 1881, p. 38) reports two cases of true vaginal chancre. The first was a girl of 18, who showed an erosive syphiloderm of the fossa naviculari, slight swelling of the right labium majus, which was more red than the other, and multiple adenitis of the right inguinal region. On examination, the meatus of the cervix uteri was slightly open and eroded; there was double adeno-lymphitis towards the lateral culs-de-sac on the sides of the uterus. On the right vaginal wall, at the junction of the upper and middle third, the finger could perceive a depressed erosion, rounded in contour, sharply circumscribed, not painful. On examination with the speculum, the cervix showed follicular erosion, together with the glutinous mucous discharge of metritis. The vaginal erosion showed all the characteristic signs of indurated chancre: the floor red, smooth, shining, non-purulent; the edges slightly elevated, and passing without a ridge into the floor of the erosion and into the surrounding tissues, of which the color was normal; not excavated or everted. The lesion was about the size of a ten-cent piece, and was seated upon the right vaginal wall, near the inferior extremity of the os uteri. It was difficult to make out the induration, on account of the laxity of the vaginal walls and the distance of the lesion from the vulvar ring. However, in passing the finger lightly over the surface in the neighborhood of the erosion a slight resistance could be perceived, as of a more resilient surface. In addition, by passing two fingers deeply into the vagina a foliaceous induration could be perceived. The lymphatics running along the walls of the vagina were somewhat enlarged; they appeared to leave the erosion and run towards the indurated post-pubic ganglia. Small ganglia could likewise be perceived in the neighborhood of the obturator foramen. On the body an eruption of roseola, with some circular erythematous patches and discrete squamous papules, could be perceived. Under a mercurial and tonic treatment the various symptoms, including the chancre itself, disappeared without any local applications having been made.

Binet's second case was that of a girl of 19, who entered the hospital for erosions about the labia and anus. To the touch there could be perceived on the posterior wall of the vagina, just within the carunculæ myrtiformes, an eroded, non-painful, finely-rugous surface, of which the floor gave the sensation of greater resiliency. On ocular examination, the lesion presented the characteristics of chancre. Its floor was grayish, the edges slightly raised, not everted or excavated, and passing imperceptibly and without a ridge into the surrounding tissues. The lesion was roundish in shape, and was the size of a quarter-

dollar. Parchment induration under and around the sore could be distinctly made out with the fingers, permitting it to be enucleated, so to speak, from the surrounding tissues. There was some vaginitis in the culs-de-sac, and there were also follicular erosions about the os uteri, with the muco-glutinous discharge of metritis. No eruption on the general surface. The patient was under observation for two weeks, during which time (probably under the influence of treatment, though this is not stated) the chancre became almost completely cicatrized, presenting a smooth, pale, violaceous tint, with a slightly depressed surface.

In discussing the causes of the extreme rarity of chancre of the vagina, Binet attributes this to the fact that the virus must either be deposited in some abrasion or in a follicle. But the vaginal mucous membrane, with its thick layers of epithelium, is extremely resistant, and is rarely eroded in sexual intercourse. Moreover, it has no open glandular orifices. Vaginal chancre is extremely rare. Fournier, in two hundred and forty-nine chancres of the female genital organs, saw only one in the vagina, and that doubtful. Binet, in one hundred and twenty-eight chancres of the female genitalia in Martineau's wards at the Lourcine, only observed the two above given. No other observers have reported the lesion.

Purpura Hæmorrhagica.—Rigal and Cornil (*Vierteljahrreschr. f. Derm. u. Syph.*, Jahrg. vii., p. 575; from *L'Union Méd.*) conclude a careful and full paper on this subject by formulating purpura hæmorrhagica gravis as a group of symptoms characterized chiefly by effusion of blood under the skin and mucous membranes, and by progressive general debility resulting from exhaustion of the nervous system. Its gravity does not depend upon the amount of blood extravasated. The hemorrhage occurs through disturbance of vascular innervation, dependent either upon irritation of the sympathetic or upon diminished action of the vaso-motor centres. Although the alteration in the quality of the blood is not without significance, yet this is so variable and inconstant that it alone, without the vaso-motor disturbance, can hardly be regarded as a cause of purpura hæmorrhagica. Purpura hæmorrhagica of an acute character may occur in the course of chronic diseases, particularly of a cardiac character, before the cachectic condition has fully developed so as to be noticeable. The alteration of the vessels in the neighborhood of the ecchymotic patches may depend upon simple ectasis of the arterioles of the corium. In studying such cases, a careful distinction is to be made between purpura hæmorrhagica and variola hæmorrhagica, scorbutus, and hæmophilia.

Urticaria following the Use of Salicylate of Sodium (*Giornale di Medicina Militare;* from Dr. Heinlein, *L'Indipendente*).—Patient suffering from inflammatory rheumatism of right knee and elbow-joints. For the first ten days one-half gramme sodii salicylat. administered every half-hour, but no improvement. Four grammes at one dose were then administered. In the evening following, temperature 38.8°; pulse 90; urine albuminous. Patient could move the affected joints. Next evening, fever nearly gone. For three days patient experienced no pain, but on the fourth returned, and four grammes again administered. A quarter of an hour later, burning pains in forehead; five minutes later, acute burning sensation in skin covering right palm of hand; slight œdema and redness of both eyelids on each side. The blush soon diffused itself over left ear, neck, and upper lip. Very soon, intense itching of skin covering abdomen, followed by diffused red blush and an urticarial eruption; pruritus quickly extended over whole body; inferior extremities attacked by the eruption and blush, but the superior not; the latter were œdematous. One hour after, eruption disappeared, and three hours after this, the blush. A few hours after attack, urine contained no albumen. In two days all symptoms had disappeared. On two different occasions subsequently the same quantity was given, with like results.

Recurrent Parotiditis in Connection with Menstruation.—M. Halvan has reported to the Medical Society of Rheims (*La France Méd.*, 1881, p. 115) the case of a patient in whom double parotiditis occurred in the middle of each menstrual period. During the patient's pregnancies menstruation was suppressed and the parotiditis did not occur. But as soon as the uterus was emptied of the product of conception, even before menstruation was again re-established, the parotids became inflamed.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, MARCH 12, 1881.

EDITORIAL.

INDEPENDENT JOURNALISM.

IN an editorial in a late number of this journal some of the difficulties which press upon an editor were portrayed, more in a deprecatory than in a defiant manner. It was a plea for mercy, rather than a challenge to combat. In the present writing we propose to put a few facts in such a light as justice may require, and, whilst we would be as far as ever from defying any one, or claiming any wisdom beyond that given to other mortals, we desire to assert as positively as we can that whatever views are advocated in this journal are believed in at the time of writing by the editor, and that all editorials mean simply what their face shows, having no ulterior, hidden object whatever.

We are led to these statements by the violent assertions in the current number of a clamorous, though not influential, journal, that certain recent editorials in the *Times* were written for the purpose of supporting the medical department of the University. As medical journalism in this country is at present not sufficiently well paid to afford a livelihood, men of energy and ability who are not in some way connected with interests outside of journalism can scarcely be procured as editors. It is, however, libellous to assert that therefore they must prostitute their position to aid such private interests. The editorial history of the *Times* under the present management was that of a persistent, bitter attack upon the University of Pennsylvania until the faculty and trustees yielded to the pressure of public opinion and adopted a reformed curriculum. Since the change the University has by no means escaped criticism; and the recent onslaught on alumni societies was first made upon that of the University.

We reiterate here what we then said, that in this country loyalty should not be to institutions or men, but to principles, and that an alumnus who shouts himself hoarse, gorges himself at a banquet, or in any way bolsters an institution the management of which he has no representation in, and the methods of which he does not approve of, is doing violence to his own manhood and an injury to the profession.

In regard to Jefferson Medical College, we have refrained from speaking as plainly as concerning the deficiencies of the University, for reasons which are obvious. How far the institution is being managed for the good of the faculty, and how far for that of its alumni and of the general profession, is a question we very willingly leave to the judgment of our readers. How far its alumni are contented with its course we do not pretend to know. The size of the classes indicates general satisfaction; but such evidence is delusive. If, however, it be correct, there is evidently much necessity for persistently enlightening the profession of the country as to the responsibilities and needs of a doctor in these later times.

It is not probable that, this spring, medical alumni societies will to any extent demand representation in college boards; but the movement is right, and agitation in this country precedes—for a long time, it may be, but still precedes—reforms. Consequently, we will in hope steadily sow the seed, whether clods continue to be thrown or not, knowing that the successful pioneer must be able to endure as well as to labor, and that the end is sure.

THE newly-elected President of the London Clinical Society, Professor Lister, took for the subject of his inaugural address "The Catgut Ligature."

CORRESPONDENCE.

LONDON LETTER.

CIRCUMSTANCES at present seem to render it desirable to give American readers some idea of the position of the Royal College of Physicians of London, conspicuous at present from its decision in the Pavy-Gull difficulty, and in the matter of a knighthood for the retiring president, James Risdon Bennett. The College of Physicians is an ancient medical body, venerable in many respects, perhaps even infirm in others. It used to consist of members and Fellows: recently it has condescended to a licentiateship, and examines students as to their fitness to practise medicine. It also examines for its membership; and a very honest, fair, searching examination it is. Its Fellows are elected,—upon what plan has never been discovered. Now, in order to give the reader some conception of the position of the College, he must first understand that the College is the portal to a consultant's position,—*i.e.*, as a physician. A man may get his M.B. or his M.D. where he will, or even not be a graduate in medicine at all, but for a position on the staff of any hospital of repute he must be a member of the College. It is the one portal to the higher grades of medicine. The examination is one of strict fairness, and has never been disputed since a very painful case some twenty years ago, when the custom was inaugurated of preserving the examination-papers for five years, so as to be at hand to be referred to if any rejected candidate thinks himself aggrieved. But the Fellowship is a mystery: it is necessary to be approved of by eleven out of fifteen men, with whom the selection lies, and canvassing is strictly prohibited. Anyhow, it is from the Fellows that the examiners are chosen and that the lecturers before the College are selected: so that the Fellows are a very important body indeed. But the selections are not made by the body of Fellows, but by a board consisting of the President and Censors. Now, this committee is a very august body, as self-electing oligarchies are apt to be all the world over. But they are not always believed in by others as utterly as they believe in themselves, and it would not be in any accordance with truth to say that there is not a great deal of dissatisfaction about the election of Fellows. One glaring absurdity is that of the arrangement with the two old English universities, whose graduates can claim (or something equivalent thereto) to be elected Fellows as soon as their four years of membership have been completed,—the minimum time. Others, no matter what their position in medicine, or their accomplished work, have to wait the will, or sometimes the caprice, of the electing body, upon whom no pressure of opinion can be exercised, unless by private influence. The late Francis Anstie had to wait a long time for his Fellowship, because he was inclined to think for himself, and would not "ko-too," as I have heard him say. The gravamen of the delay is as follows. The Fellowship is withheld from members for unprofessional conduct; that is well known. Its delay, then, is apt to cause misapprehensions, and to mix up offenders and non-offenders very unpleasantly. Some little time ago, C. J. B. Williams tried to bring about some changes, so that the members should be placed more equally as regards their chances of being elected Fellows; but without avail. The College of Physicians, then, is a conspicuous body, possessed of very considerable powers, and responsible to nobody but itself, or rather its governing or ruling committee.

Now, part of its powers is its control over its Fellows and members, who are advised to live in harmony with each other and to treat each other with courtesy, nothing being said about their treatment of outsiders. A consultation among more than two of this select circle contains formalities not without interest; but these cannot be gone into here. Like other bodies possessed of powers, they have a machinery by which they can enforce compliance with their regulations: so an aggrieved Fellow (or member, though this latter would probably scarcely think it worth his while to ask to have his grievances considered) can cite another before the committee and have his conduct looked into. Censure follows disapprobation. Thus, it is said, the College "guarantees the conduct of its Fellows and members." Unfortunately, however, for the venerable College, one of its Fellows is a man of great hardihood of character, unsoftened by gentle lineage, viz., Sir William Gull, the well-known medical baronet. Sir William Gull has been a source of much tribulation to the senators of the profession,—the Board of Censors of the R. C. P. In the notorious Bravo poisoning case the baronet did not behave well towards George Johnson, Professor of Medicine in King's College, famous for his work in relation to diseases of the kidney, and for his difference of opinion from Sir William Gull and Dr. Sutton as to the changes in the arterial system found along with chronic renal disease,—a man, indeed, who deserves well of the profession. He appealed to the College, who decided that he had been aggrieved; but their censure was almost inarticulate. It had very little, if any, effect upon the headstrong baronet, who has not been long in again flaunting in its venerable face his indifference to its opinions, expressed or other. Some little time ago, your readers will remember, while the recent unhappy dispute at Guy's Hospital was in progress, a nurse put a patient into a bath with such neglect of proper precautions that she was tried for manslaughter, condemned, and imprisoned for her practice. The unlucky patient was under the care of Dr.

Pavy, whose researches on food, on diabetes, and on kindred subjects have procured for him world-wide reputation, and deservedly. The patient was the subject of pulmonary tuberculosis. Sir William Gull, without any consultation with Dr. Pavy, appeared in the witness-box, in virtue of his position as consulting physician to Guy's Hospital, in favor of the defence. This was an assumption, as regards the position of consulting physicians, felt by most persons as undesirable, to say the very least of it. The baronet gave it as his opinion that the unfortunate woman died of brain-disease, and that the painful incident of the bath had nothing to do with the fatal result. What effect this evidence had upon the jury is illustrated by their verdict. I have told you in a recent letter how the undergraduates of Cambridge received the medical baronet last August, when he appeared for his D. C. L.: there was no possible question about their disapprobation. Dr. Pavy complained to the College of Sir William Gull's behavior. The decision was as follows:

"January 12, 1881.

"The President and Censors of the Royal College of Physicians, having carefully considered Dr. Pavy's complaint and Sir William Gull's reply to that complaint, do not deem the character of the evidence which a Fellow or a member of the College has given on oath in a court of justice a proper subject to investigate, when the court has expressed itself satisfied in regard to the truthfulness and sincerity of the witness.

"They consider Sir William Gull, holding the opinions he expressed on oath, justified in going into court. They are further of opinion that Dr. Pavy's diagnosis and treatment of the woman afford no grounds for any remarks calculated to disparage his well-deserved reputation as an eminent and skilful physician."

Here follow the signatures of the president and four others. Now, this is "blowing hot and cold" at once. The baronet is held to have had "no grounds" for what he said on oath, but, believing what he did, he was "justified in going into court." This at least is what it means, if the language means anything. There lies a subtle satire underneath this quiet censure, as if the College declined to be the keeper of Sir William Gull's conscience. However, no gossip tells of the baronet feeling in any way rebuked or disconcerted by the decision; and probably he will run the risk of their disapprobation again, if so minded. But the example of so well known a physician being a repeated offender militates most materially against the authority of the College as a controlling body. In the General Rules for the behavior of medical men giving evidence in law-courts, in the "Medical Directory," it is written, "A medical witness should bear in mind that he should be well prepared on all parts of the subject on which he is about to give evidence." And, again, "No opinion should be given for which the witness is not prepared to assign reasons." Now, whether Sir William Gull set a good example to the profession generally, irrespective of his alleged duty to the College, or not, is certainly open to question. There is no question, however, that his example is not calculated to add to the dignity of the R. C. P., or to inspire dread in potential offenders.

Now for the consideration of the second matter, the knighthood of Dr. J. Risdon Bennett, the retiring president. I have been censured for asserting that socially the profession is not properly recognized in this country; but this little event shows how far the medical profession is beneath the sister professions, the law and the church. The dignitaries of the law are many; its head is the Lord-Chancellor. The church has two archbishops and the bench of bishops, lords spiritual. The medical profession can boast no peer in Great Britain or Ireland. What says the *British Medical Journal?*—"The outgoing president of the College is to receive knighthood. That is a dignity which is, perhaps, better reserved for civic personages; and if the College of Physicians is to receive an honor of the kind, it should be by the dignity of a baronetcy; and the College would, in the opinion of many, do better if, in future, it requested its outgoing president to decline knighthood if proffered in cases where there are difficulties in the way of conferring a baronetcy. A dignity more appropriate to the position of the College and the grades of the medical profession would be a K.C.B.-ship or the position of a privy councillor." The latter seems especially appropriate. The *Lancet's* remarks are very cautiously expressed, but are to the same effect. The *Medical Press and Circular* satirically remarks, "It will, we feel sure, be felt that Dr. Bennett is well deserving of a recognition of the amiable and excellent way in which his duties to the profession have been discharged during his tenure of office; and we congratulate him upon the appropriate manner in which he is about to be rewarded." There is an uncomfortable bluntness about the words "difficulties in the way of conferring a baronetcy," as if a baronetcy was for some occult reason withheld in this case. The last president, Sir George Burrows, was made a baronet. Why, then, is Dr. Bennett only to be a knight? "Comparisons are odious." The subject excites a good deal of comment in medical circles, if little elsewhere. It appears that baronetcies are not bestowed upon members of the medical profession unless they have been "court physicians;" and Dr. Bennett, though consulting physician to St. Thomas's Hospital, has been in repute chiefly in the city rather than in the court. Until he was made president of the

College, he resided in Finsbury. He is a Non-conformist, and it is said that his practice lay mainly among his co-religionists. He is the first president not belonging to the Established Church. Against this could not be set the fact that Dr. Bennett had contributed much to medical literature. He is the author of the Fothergillian prize essay for 1842 on "Acute Hydrocephalus," the Lumleian lectures on "Cancerous and other Intrathoracic Growths," 1871, and a translation of Dr. Kramer's "Treatise on the Ear,"—no very formidable list. It further appears that Dr. Bennett is the father of a family not exclusively confined to daughters. Had the latter been the case, the matter would have been considerably simplified. But Dr. Bennett has at least one son, a member of the profession, in general practice, and who has not as yet made his début in the higher rank of consultants. He is married and has offspring, and a baronetcy is inheritable. A baronetcy requires means to uphold it, and many a man has had to be content with knighthood when he has had male offspring. The "difficulties" are complicated; but, whatever some may think due to the president of the Royal College of Physicians, others think that, as regards the interests of the individual, Dr. Bennett is better off with the simple knighthood than with a baronetcy which might form a troublesome inheritance. It is, of course, unfortunate when the aspirations of a profession and the interests of an individual clash, and it seems a pity now that the choice of the College fell just where it did; but that is done and ended.

The *British Medical Journal* reiterates its poignant grief at the want of consideration of "the dignity of medicine," and quotes an evening contemporary to this effect: "By the favor of the crown, Dr. Bennett is to become a knight. If the president of the Royal College of Physicians thinks that knighthood can add to his dignity, a knight no doubt he will be; but the announcement seems to show that now, as in the past, the least-prized honor is held to be good enough for a leading member of the noblest of professions." Contrast with this the positions held by members of the profession elsewhere, as Virchow in Germany, Hyrtl and Rokitansky in Vienna, Larrey, Nélaton, and Broca, in France. Others have held honorary positions. Bacelli is Minister of Public Instruction in Italy; Alvarenga is a royal councillor at Madrid. It is in Great Britain, with an intensely liberal government in office, too,—which greatly adds to the sense of wrong (if it had been the late Conservative government, then a "liberal" profession could have consoled itself by thoughts of old-established class-distinctions; but a "radical" government, and the cup of its bitterness brims to running over),—in the country which is in the van of the world, that the medical profession has to see its head have to be satisfied with a second-rate distinction. It reminds one of what the late George Eliot said of Rufus Lyon, the Dissenting minister of Treby: "His gifts were admired, and tears were shed under best bonnets at his sermons; but the weaker tea was thought good enough for him; and even when he went to preach a charity sermon in a strange town he was treated with home-made wine and the smaller bedroom." So the outgoing president of the College of Physicians has, during his term of office, been asked to give the crown the benefit of his advice in difficult matters; but it does not seem that therefore the position of a privy councillor should be given him. If his advice was deemed worth asking, surely it was worthy of some such recognition. But then the medical profession in the services, in civil life, and elsewhere have to be satisfied with "the weaker tea" and "the smaller bedroom." Possibly the College will feel thus negatively encouraged to select for the future as president a member of the profession in whose case there will not eventually turn out the "difficulties in the way of conferring a baronetcy."

Probably the dignity of the profession would be more consistently consulted if it was distinctly understood that the presidentship of the College is not to be an indirect way towards approaching a baronetcy. Few men in the profession can afford such an honor; and it would be wiser not to place the profession in such mournful contrast with the law and the church as regards honors and titles. The profession is a noble calling, and it is unwise to mix it up with rewards which are inadequate to its real merits. It is dragging the reputation of the profession in the dust, this petty squabbling about the lowest of titles. Mr. Gladstone remains a plain "Mr.," and a knighthood cannot produce such a metamorphosis of the individual as can be very gratifying to either him or his relatives in the case of a president of the College of Physicians. But the College seems to be coming to evil days: as I write, the *British Medical Journal* takes it to task for the composition of its council, in which the provincial Fellows are conspicuous by their absence. It really must begin to set its house in order if it aspires still to be the guide in matters medical, or an efficient monitor. The medical world was scandalized lately by advertisements in non-medical papers of a popular medical book written by one who has been on its council and is now a curator. If those who stand high in its ranks so openly defy it, what restraining power can the College possess? It should either reform itself or abdicate. Fortunately, no such squabble about honors for the outgoing president can occur for a few years at least, as Sir William Jenner is the next president, and in him the profession and the public alike have the utmost confidence.

J. MILNER FOTHERGILL.

PROFESSIONAL SECRETS.

PHILADELPHIA, March 1, 1881.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Dr. F. R. Sturgis's admirable letter in the last number of your journal, strong as it is, does not bring out all the objectionable features of the pending bill as to the testimony of physicians. It not only compels us to be silent and unwilling accomplices in known crimes, but it will often in civil suits be a bar to justice. In conversation with one of our leading civil lawyers lately, he called my attention to the fact that it would prevent the doctor's giving any testimony as to the testamentary capacity of patients making wills, and as to the mental condition of any patient, whether insane or not.

When the bill was first proposed, I suggested to the committee that in the phrase "neither allowed nor compelled to disclose," etc., the word "allowed" be stricken out. Attention was again directed to the objectionable word in an editorial in the *Medical News and Abstract* for December, before the bill was introduced; yet the word "allowed" has been retained, and has compelled an opposition from both doctors and lawyers, which I hope will be effective in amending the bill before it is passed, if indeed it be wise to pass it at all. That the New York State Medical Society is endeavoring to repeal an almost identical law is the strongest argument against it,—the argument of experience.

Very truly yours,
W. W. KEEN.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA ACADEMY OF SURGERY.

STATED MEETING OF JANUARY 3, 1881.

The President, DR. S. D. GROSS, in the Chair.

COMPLETE OSSEOUS ANCHYLOSIS OF THE KNEE TREATED BY REMOVING A WEDGE OF BONE.

DR. THOS. G. MORTON presented the following notes of the case:

About two years ago, the patient, John J. B., æt. 15, while chopping wood, accidentally wounded himself in the right knee with the axe, the blade entering deeply just to the right of patella, opening the joint. As a result, anchylosis took place; the limb assumed the position of flexion of leg towards thigh, and finally the bony anchylosis became complete, the function and original structure of the joint being completely abolished.

When admitted into the Pennsylvania Hospital, March 9, 1880, the limb presented the following appearance. The entire lower extremity has undergone considerable muscular atrophy; motions of hip- and ankle-joint normal. The leg is flexed at knee to rather more than a right angle, and the anchylosis of the joint is absolute. The patella appears to be slightly displaced outwardly, and is firmly adherent and immovable. The hamstring tendons are very tense. The general condition of the patient is excellent. Kidneys normal.

On March 12, after etherization, I excised with the saw a wedge-shaped piece of bone, the base of which included the patella and was two and a half inches in width. It was so cut as to make the wedge a truncated one at its apex, so that when removed, and the sawn surfaces brought into close contact, the leg would be brought not quite straight, but in a slightly flexed position; the patient thus being enabled, after recovery, to walk upon the ball of the foot, obviating the necessity for walking in a stamping manner upon a leg brought out perfectly straight.

After the ligation of a few articular vessels, the flap, which was a large, anterior, U-shaped one, was approximated by interrupted sutures of silver wire, a dressing of carbolized charpie was applied, and the limb placed upon a double-inclined plane of very slight degree of inclination, so that the sawn surfaces lay in exact apposition. Prescribed iron and quinia and solution of acetate of ammonia.

March 20.—The patient undoubtedly has erysipelas. The flaps very much swollen. Four stitches removed. Very free discharge of pus. Dressed with ung. zinci oxid. Temperature, 103.5°. Coincident with the rise in temperature a small amount of albumen appeared in the urine, but no casts were found.

March 29.—Albumen has disappeared. Temp. 99°. Erysipelas has subsided, but pus has burrowed back upon the outer side of thigh. This opened, and drainage-tube was inserted.

April 6.—Tinct. ferri chlor. stopped. Wounds, which now look well, dressed with carbolized charpie.

April 15.—Stopped quinia. The opening in thigh has closed; the line of flap granulating well.

April 26.—Some union exists between the bony surfaces.

May 18.—Granulations fungous. Applied sol. cupri sulph. gr. iv to f℥j.

May 28.—Bony union quite firm. Line of flap almost healed. Leg removed from double-inclined fracture-box and laid upon pillow.

June 4.—Plaster dressing applied, and, when set, cut and reapplied. Wound entirely healed.

June 20.—Walking with assistance of crutches.

July 2.—The operation was a success, and the result a perfect one. The limb is in position of slight flexion at the knee, and when he stands erect the ball of the right foot comes to within two and a half inches of the ground. The bony union is very strong, there being

no motion at all at the seat of operation. He was ordered a brace, consisting of a shoe with thick sole and high heel, side-irons, and knee- and thigh-brace.

THE TREATMENT OF FRACTURE OF THE LOWER END OF THE RADIUS.

Dr. R. J. Levis exhibited three patients under treatment for fracture of the lower end of the radius. These fractures had been produced in the usual way, by falls in which the weight of the body is received on the palm of the hand. Each of these cases had shown in a marked manner, at the time of the receipt of the injury, the ordinary deformity characteristic of the fracture. He presented the cases, at from about a week to three weeks from the receipt of the injury, to show the effect of complete reduction of the fracture and maintaining apposition in his moulded splint. The patients were entirely free from pain, and when the splints were removed for examination of the parts, there was good control of the movements of the wrist and hand, and no evidence existed of any of the unfortunate sequences which, it is admitted, generally follow the fracture.

Dr. Levis remarked that, from extended practical observation and the examination of pathological specimens, the following deductions may be summarized:

The ordinary fractures of the lower end of the radius, produced by falls on the extended palm of the hand, are situated at from one-quarter to three-quarters of an inch above the articular surface, and are transverse in direction. The characteristic deformity of the fracture, as originally described by Colles, is correct, but he erred in locating it at an inch and a half above the carpal extremity of the bone.

The theory of the fracture as described by Barton, "a quite small fragment broken from the end of the radius on its dorsal side," has not been verified by clinical experience or by pathological observation, and is not in accordance with the true mechanism of the production of the fracture.

The force which produces the fracture is, for the most part, transverse to the long axis of the bone, and tends only to produce transverse fracture. Violent over-extension of the hand is the important factor in its production, and the bone breaks immediately above its strong ligamentous connection with the wrist and hand. Force transmitted through the anterior carpal ligament is the immediate cause of the fracture.

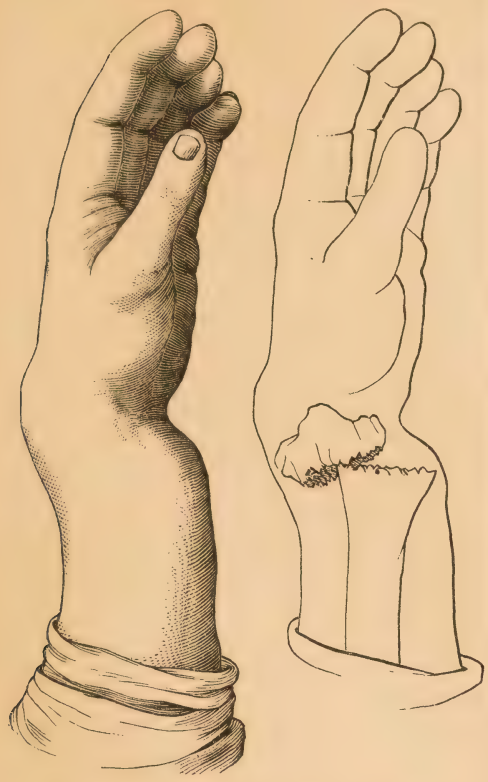
Impaction, to a small extent, may occur by the posterior edge of the upper fragment being driven into the cancellated structure of the lower fragment, but it is not an important complication, and should not prevent coaptation.

Comminution is usually vertical splitting, and is caused by the same mechanical action as that which tends to produce impaction.

The displacement of the lower fragment backward and upward can always be overcome by strong longitudinal traction associated with forced flexion; and, in uncomplicated cases, the fragments, when completely reduced, will remain in apposition without any retentive apparatus.

When comminution by vertical splitting exists, and the fracture has been produced by great force, rupturing the surrounding dense structures, apposition may usually be maintained by keeping the wrist in a state of flexion, with the aid, sometimes, of the pressure of a dorsal pad.

The unfortunate sequences of the fracture, as generally treated, are due to *imperfect primary reduction of the displacement and the want of proper retention in apposition*. The usual long-continued impairment of function of the wrist and hand, and the painfulness which generally follows, are not due, as asserted by most authorities, to inflammation in the sheaths of the tendons, but *simply to pressure and irritation caused by the unreduced fragments*. That such impairment of function and suffering result from the ordinary incorrect treatment of the fracture by surgeons generally, nearly all surgical authorities attest.



In support of this statement Dr. Levis quoted the opinions of Hamilton, Gross, R. W. Smith, of Dublin, Bryant, J. R. Barton, Callender, and Agnew.

Dr. Levis said that many years ago, whilst he was endeavoring to investigate the cause of the usual bad sequences of the fracture under consideration, he recognized its almost uniform position and direction, and concluded that its transverse direction, at that, the thickest part of the bone, could not be produced by longitudinal force, as had generally been taught. Examination of a number of cases of chronic deformity following the fracture, and of many museum specimens, demonstrated the fact that the mechanism of the fracture had not in the treatment of those cases been understood, and that the fragments had never been brought to proper apposition, and thus deformity, with its attendants of more or less suffering and disability, had continued through the lives of the patients.

He did not deny that fracture of the lower end of the radius may be produced by varied direct and indirect forces, and consequently show as much variety in its mechanism. But the form of fracture which is of most frequent occurrence, presenting the familiar characteristics, and which in its results, as ordinarily treated, is truly the opprobrium of the surgery of fractures, is a simple transverse fracture, very near to the carpal end of the bone, can readily be placed in apposition, and should not be followed by deformity or permanent disability. He had clinically taught and practised on these principles since the year 1861, and had asserted them in an address before the Medical Society of the State of Pennsyl-

vania in 1874, and again in a paper before the same body in 1879.

FIG. 1. FIG. 2.

The accompanying cut, Fig. 1, is from a cast taken from a recent case by Dr. Harte, one of the resident surgeons of the Pennsylvania Hospital, which well shows the characteristic deformity of the usual transverse fracture of the lower end.

The schematic outlines, Fig. 2, represent the relative position of the fragments.

The usual errors in the treatment of this fracture are in not recognizing the position and direction and the peculiar displacement of the lower fragment, and in not producing a correct apposition of the fragments. There is also the customary error of endeavoring to treat a fracture of a curved portion of bone by a straight surface of splint, which tends, after complete reduction, to again displace the lower fragment backwards. A pad fitted to the anterior radial curvature may be placed on a straight splint, but it is liable to slip out of position, and its action to be the reverse of what it is intended to accomplish. The moulded splint has the merit of following the curve of the anterior surface of the lower end of the radius, and the imbedding of the wrist and hand in corresponding portions of the splint secures the curve in its proper position with reference to the fracture.

The fixation of the wrist and hand in a state of slight flexion obviates the tendency of the lower fragment to upward and backward displacement. The moulded splint is of flexible metal, so as to be conformable to any fleshy or attenuated forearm. It is supplied by all the surgical instrument-makers at a cost of one dollar.

Dr. John H. Packard agreed with Dr. Levis in regard to the importance of perfect reduction, and showed a specimen of fracture of both radii, taken from an old woman, who died from other injuries about five days after admission to the Episcopal Hospital. When admitted to the institution, she was wearing two straight splints on each forearm, but the fragments had not been replaced. The fact of the non-reduction was very easily demonstrated. Coaptation of the fragments was effected without great difficulty, and maintained by simple means, viz., the application of thin slips of wood, properly shaped, along the radial edge of the anterior surface of each forearm. These were retained in exact position by means of broad strips of adhesive plaster.

Dr. Packard urged that the usual method of procedure, by mere extension, and drawing the hand towards the ulnar side, was ineffectual for reduction. By extension, followed by flexion, and moulding with the surgeon's fingers, the normal contour of the bone could be best restored; and, in order to maintain it, the concavity of the anterior surface of the radius at its lower part should be preserved.

Bond's splint, as commonly employed, is in his opinion a most fruitful source of deformity in these cases. He had used Dr. Levis's tin splint with satisfaction.

Dr. J. E. Mears inquired if there was not a difference between fractures entering the joint and those which were not thus complicated.

Dr. Levis replied that there would be more likelihood of arthritis occurring in the former case, but said the results were usually good if replacement was perfect.

Dr. T. G. Morton thought that immediate reduction under ether was of the greatest importance, and the kind of splint of little moment.

Dr. D. H. Agnew believed the mechanism of the fracture to be tension of the anterior radio-carpal ligament, and that the injury could be well treated by the method of Bond, with the hand in the natural position of rest. In his opinion Dr. Levis's plan acted by the extensor tendons being put on the stretch and holding the lower fragment down. He had treated cases in the perfectly straight position with good results. Passive motion should be begun early.

Dr. W. H. Pancoast stated that he was accustomed to use two straight splints with appropriate pads, and believed that the line of fracture was above the ligaments.

WOUNDS OF THE BLADDER.

Dr. Morton presented a specimen of wound of the bladder produced in what was supposed to be either a suicidal attempt or an endeavor to relieve a distended bladder by opening the abdominal wall. The man had been found with an incision in the right side of the abdomen made by a sharp instrument and apparently cut from below upwards. The bladder showed a small wound, and the peritoneum the commencement of inflammation. In the urethra there was found at the autopsy a white bone stud, such as used in fastening shirts. This may have produced retention, and caused the man to endeavor to evacuate the bladder by an incision. No history was obtainable, because the patient died on the way to the hospital.

Dr. Morton also showed a specimen of large rupture of the bladder taken from a heavy German, who fell over a stool and struck the abdomen. There was urine extravasated among the intermuscular spaces of the abdominal wall, but not much urine was found in the peritoneal cavity.

Dr. Wm. Hunt referred to an instance of perforation of the bladder by a sharp stick, which entered the perineum near the coccyx and opened the bladder. The wound was in a good position for drainage. The boy was catheterized for a time, but in about five weeks was able to pass his urine by the urethra. He finally recovered.

Dr. S. W. Gross had read of a similar case, where the leg of a stool entered the rectum through the anus and tore open the bladder. The patient recovered. The question of operation in cases of rupture of the bladder comes up for decision in some instances of the injury. In an early edition of his work on the Urinary Organs, Professor S. D. Gross had recommended opening the abdomen and mopping out the peritoneal cavity. Walter, of Pittsburg, Heath and Willitt, of London, have done abdominal section in cases of rupture of the bladder with extravasation into the peritoneal sac. Walter's case recovered; and Mason, of New York, and Walker, of Boston, have successfully performed perineal incision for free drainage in injuries of the bladder.

Dr. R. J. Levis believed it advisable, when urine was extravasated, to make a free opening in either the perineum or the supra-pubic region.

FATAL HEMORRHAGE FROM PERFORATION OF THE EXTERNAL ILIAC ARTERY DUE TO DOUBLE PSOAS ABSCESS.

Dr. R. J. Levis showed the specimen taken from a case, with this history:

Sarah J. T., aged 31 years, colored, states that she had never been a robust woman. Her present trouble began last May with pain in the back, etc. About six weeks ago she was compelled to go to her bed. About four weeks ago an abscess pointed and opened about an inch below the anterior superior spine of the ilium, discharging a large quantity of pus daily. When admitted, she had a long superficial sinus running from the opening towards the pubes, which was opened on a director. Her general condition was bad, and she was very weak and anæmic: hence she was placed on iron, quinine, stimulus, and nourishing diet. In spite of the careful attention she received, she lost flesh, and the discharge increased. The anterior superior spinous process of the ilium became denuded of periosteum, and bed-sores made their appearance on the prominent points of the back.

On December 25, 1880, shortly after being dressed, she had a severe hemorrhage coming from the abscess, from which she died in a few minutes.

Post-mortem examination showed two large psoas abscesses, filling up both iliac fossæ, the one on the left side discharging into the right through a sinus between the spinous processes of the third and fourth lumbar vertebræ.

The iliac vessels were dissected away from their attachments with the surrounding tissues on both sides, and a small ulcerated spot on the coat of the external iliac artery of the left side, about the size of a large goose-quill, showed a perforation which had allowed fatal hemorrhage. Both abscesses were filled with coagulated blood.

DEATH FROM HEMORRHAGE OCCURRING IN A CHILD FOURTEEN DAYS OLD, DUE TO A SCRATCH OF THE LIP.

Dr. John H. Packard recorded this case, in which a mere scratch, laying bare the cutis vera, possibly produced by the child's own finger-nail, began to bleed, and could not be restrained by astringents and the various means employed. The hemorrhage began when the child was seven days old, and recurred, until death took place at fourteen days.

JOHN B. ROBERTS, M.D.,
Recorder.

REVIEWS AND BOOK NOTICES.

A PRACTICAL TREATISE ON TUMORS OF THE MAMMARY GLAND; EMBRACING THEIR HISTOLOGY, PATHOLOGY, DIAGNOSIS, AND TREATMENT. BY SAMUEL W. GROSS, A.M., M.D. New York, D. Appleton & Co., 1880. 8vo, pp. xi., 246.

By accidental neglect of the reviewer, our notice of this valuable book appears somewhat late,—not, indeed, until the work has become widely and favorably known and gained its fully-deserved recognition by the medical profession.

The book is particularly interesting, for the following reasons. 1st. It is the only complete systematic treatise on the subject ever written; it is not a mere compilation, such as many books of this kind are, but is the result of prolonged personal research, sound thinking, and a conscientious analysis of the literature. 2d. It is written by an experienced surgeon, who is at the same time a surgical pathologist, and who, as is well known, has seen more and studied more tumors than any other living surgeon of the same age: he has fully availed himself of the unusually large material at his disposal. 3d. The book is of great practical value, and not bulky; it is attractively written, well illustrated, clear, and accurate.

This is not too much praise, as the following brief review, or, still better, a study of the book, will show.

Hueter, in Germany, was the first to suggest the writing of regional treatises on tumors. Abroad several useful monographs of this character have appeared; but Dr. Gross is the pioneer in this country in writing an original scientific treatise on tumors of the mammary gland, having shortly before published his investigations on sarcoma of bones.

In writing the book now before us, Dr. Gross has produced a treatise on tumors in general, for the neoplasms occurring in the mammary gland represent nearly all the tumors with which the surgeon ever comes in contact. The book commends itself to the notice of practitioners, as it embodies in a condensed form all modern views upon the subject of tumors, a feature for which one may look in vain in the standard text-books of surgery. The subject of synonymes, which is so much abused by various authors, is very much clarified by Dr. Gross. The author's deductions are founded upon the careful analysis of nine hundred and two cases of tumors and of sixty-five cases of cysts, all of which have been subjected to careful microscopical examination. One hundred and thirty-six of these were contributed by Dr. Gross himself; the rest he collected from the experience of others and from literature, exercising great discretion in selecting only those of recent date and reliable authority. Though he gives due consideration to the opinions of other authors, Dr. Gross deals only in facts arrived at through patient, careful study and experience, giving no indulgence to speculation.

The classification adopted by Dr. Gross is the histogenetic one of Virchow, as modified by Lücke, agreeing, however, with Birch-Hirschfeld in classifying the adenoma together with the carcinoma, terming the first typical and the second atypical epithelial growths. Contrary to Lücke, myxoma is excluded from the embryonal connective-tissue substances.

The evolution and transformation of mammary neoplasms are carefully and exhaustively treated, the author adhering closely to the blastodermic derivation of the same.

The etiology of tumors is duly considered, and valuable information can be obtained from the chapter on this subject.

Speaking of the varieties of tumors met with in the mammary gland, and the relative frequency of their occurrence, among other valuable statistical tables the following figures are given: of 777 tumors, 640 were carcinomata, 60 sarcomata, 50 fibromata, 18 adenomata, and 7 myxomata.

All the chapters on individual tumors are extremely well written, especially the one on carcinoma. Concerning adenoma Dr. Gross differs widely from other authors, and, although the chapter has been carefully worked out, it is not altogether free from objections, as, for instance, the division into tubular and acinous adenoma. In the first place, the tubular and acinous formations are always found in one and the same tumor in its different parts, unless too much disfigured by cystic change. Careful investigation has certainly demonstrated that every adenoma has both a tubular and an acinous structure in the different parts of its parenchyma, sometimes the one, sometimes the other predominating. The same can be said of carcinoma, where in one part the microscope reveals a fully-developed scirrhus, and in another part retrograde changes and excessive proliferation of connective tissue; while the same scirrhus in its later life-history gives the appearance of the so-called atrophying scirrhus. Hence a thorough examination of a tumor in its different parts cannot be too strongly recommended, and unnecessary subdivision can thus be avoided.

The chapter on cysts merits careful perusal, as it gives evidence of a thorough understanding of the subject, which could have been attained only by a rich experience. The naked-eye appearances, the physical properties, and the degenerations of tumors are exhaustively discussed.

We believe that in the diagnosis of tumors during life Dr. Gross cannot be surpassed. In the chapter on this topic he gives an admirable table on the differential diagnosis between carcinomatous and non-carcinomatous tumors, where the following points are conclusively considered as diagnostic points: Age of development — Social condition— Menstrual function — Hereditary predisposition — Injury and other exciting causes— Situation—Outline — Consistence—Multiplicity—Volume and rate of growth—Mobility— Relation to breast — State of nipple — Discharge from the nipple—Superficial veins— Condition of the skin—Fixation to the chest —Both breasts affected — Ulceration — Lymphatic glands — General condition — Local recurrence — Duration of life.

Another table gives the differential diag-

nosis between cystic and solid tumors; and, finally, the author draws fifteen conclusions from his own experience, relating to the differential diagnosis of individual tumors, which are unique in character and not to be found elsewhere.

As regards treatment, which comprises one of the most valuable chapters in the work, early removal is advocated, and the contra-indications for surgical interference are also most carefully pointed out. H. F. F.

GLEANINGS FROM EXCHANGES.

THE CATGUT LIGATURE.—In an article on "Some Points connected with the Treatment of Wounds" (*Brit. Med. Jour.*, 1881, vol. i. p. 150), Dr. William Macewen, after speaking of the disadvantages attendant upon the use of the silk ligature, formerly in universal use, says what was wanted was a substance which would be efficient as a ligature and which would not produce irritation in the wound. In catgut these desiderata are found realized. It is Dr. Macewen's opinion that secondary hemorrhage is not so often heard of since the introduction of catgut ligatures as when silk was used. The only objection to their use is that they soften within forty-eight hours, and so are not proper for use on large vessels. Mr. Lister has recently, it is said, discovered a method of preventing this rapid softening; but he has not yet made his procedure public.

Dr. Macewen has devised a chromicized catgut ligature, which he thinks will gain the end in view. These ligatures are prepared by making first a watery solution of chromic acid, one to five; then one part of this solution is added to twenty of glycerin. This forms a dark-greenish compound, in which the hanks of catgut are inserted and retained for seven or eight months, the bottle containing them being occasionally shaken. At the end of this time the catgut has acquired a semi-translucency, and has a dark color like preserved ginger. It is then ready for use, and is stored in a solution of carbolic acid and glycerin (one to ten). The size of the catgut which is of most use in ligating large arteries (excluding such as the innominate) is the medium; and this size has been very frequently tested since 1877. This chromicized catgut does not produce irritation, and Dr. Macewen relates several cases in which the ligature was simply absorbed and never heard from. Experiments show that the earliest date of absorption of the chromicized catgut is nine days after application, while the longest period is nineteen days, the average being a fortnight. This quality of durability makes the catgut peculiarly fitted for other uses than the ligation of large vessels in their continuity, such as the approximation of the pillars of the ring for the radical cure of hernia. In conclusion, Dr. Macewen says that the physical qualities of the catgut are such as to commend it as a ligature. It is very pliable, having very slight elasticity, but not sufficient to cause it to yield before the impulse of the current of blood in the largest arterial trunks. A firm secure knot can be tied on it. Physiologically it produces no irritation in the wound. It resists the action of the tissues for about a fortnight. It disappears about the twentieth day. It is eventually absorbed by the tissues, as is evinced by their action on the chromicized stitches. Chromicized catgut prepared in a stronger solution will resist the action of the tissues for a much longer period. Dr. Macewen suggests that it may take the place of hairs for drainage-purposes.

HYPODERMIC INJECTION OF ERGOTIN AS A COUGH-SEDATIVE.—Dr. James Allen, in a communication to the *British Medical Journal* (vol. i., 1881, p. 158), says that ergotin, injected hypodermically, in doses of from one to three grains, is a remedy of notable power in allaying coughs of various lung-conditions, and in diminishing sputum. Unlike some potent drugs, that occasion general distress out of proportion to possible good results, ergotin is not followed by any constitutional disturbance. However injected, there is local irritation: if into the subdermal connective tissue, suppuration may take place; it should be thrown deeply into a muscle, as the deltoid. In a small proportion of cases it entirely fails. Sedative effect persists for a day or two, and is likely to control a cough that has defied even the most cunningly devised linctus. In the severe harassing cough of advanced phthisis, not unfrequently exciting sudden fatal hæmoptysis, ergotin is indicated as a prophylactic. The internal administration of the liquid extract of ergot, in moderate or tolerably large doses, does not seem to have the same effect.

EFFECT OF A TOO LARGE DOSE OF GELSEMINUM.—Dr. De Wolfe (*Brit. Med. Jour.*, vol. i., 1881, p. 193), while suffering severely from facial neuralgia, took ten minims of the fluid extract of gelseminum. In half an hour he took another dose of the same strength. In fifteen minutes after the second dose he was so drowsy he could scarcely keep awake. There was great pain over the frontal region; no neuralgia. The pulse was weak and intermittent. He had cold, shivering, and dizziness. The pupils were slightly contracted, and there was a general feeling of collapse. He took a cup of very strong tea, and in five minutes was very sick, vomiting freely, but not feeling any better. He had then given to him a glass of strong brandy-and-water, which was repeated in half an hour. In two hours he was all right again. The neuralgia had gone, and has not since reappeared.

RUPTURE OF THE SPLEEN FROM A FALL.—Dr. Henry Tomkins gives (*Lancet*, vol. i., 1881, p. 134) the case of a woman who fell from a box three feet high, on which she was standing, striking her left side against a corner

of it. She complained at the time of being hurt, but not severely, and a few minutes after she resumed her work. From that time onward she complained more or less of her side, saying that "it caught her breath" and that she felt as if she had "a lump there." Her friends could not detect anything abnormal to sight or touch; there was no bruising. Three weeks after the accident she complained one evening of an increase in the pain, referring it now to the epigastrium. The next morning she was found dead in bed. The autopsy showed the body very anæmic; the abdomen was distended, and the peritoneal cavity filled with dark sanious fluid and numerous large soft clots. Beneath the edge of the ribs on the left side, extending across the epigastrium, was a huge dark mass, which proved to be the spleen. In size, speaking roughly, it was as large as the liver, and weighed at least four pounds, probably more. On the under surface the organ was ruptured, and, cutting into it, it was found to be hollowed out into a large cyst filled with soft coagula. All the other organs of the body were healthy and bloodless.

MISCELLANY.

PROFESSIONAL RELATIONS BETWEEN PHYSICIANS AND DRUGGISTS.—A committee of conference representing the regular pharmacists of this city on one hand and the Medico-Legal Society on the other have recently discussed the much-vexed question of the relations between the druggists and the doctors, reaching the conclusions expressed in the following resolutions:

1. "*Resolved*, That the subject of controlling the patent-medicine evil be referred to the Philadelphia Medico-Legal Society, and that they be requested to send a committee to druggists, requesting them to place out of sight patent-medicine signs and medicines, and discourage the sale of nostrums; said druggists to sign their names to such an agreement, and physicians promising, on their part, to throw all the weight of their patronage to such pharmacists as comply with the request."

2. "*Resolved*, That physicians, when writing a prescription which they do not wish renewed, should write on the bottom of such prescription, '*Do not Renew*,' and also inform the patient of the fact, in every case."

3. "*Resolved*, That as the diagnosis and treatment of diseases belong to the province of a distinct profession, and as a pharmaceutical education does not qualify the pharmacist for these responsible offices, he should, where it is practicable, refer applicants for medical aid to a regular physician."

The promoters of these resolutions suggest that lists of physicians and pharmacists who agree to the principles set forth in the agreement given below shall be posted in some public place where they may be seen for reference, while the pharmacists are requested to put proprietary and patent medicines out of sight and to discourage their sale.

And the regular medical profession are earnestly urged to withdraw all prescription patronage from all medicines patented or controlled by trade-marks, copyrights, or secret formulæ; and by withdrawing their business support from patent-medicine manufacturers and manufacturing pharmacists who aim to subsidize not only legitimate medical practice and legitimate pharmacy, but also the medical and pharmaceutical journals, with garish advertisements of patent and trade-mark pharmaceuticals, legitimate pharmacy and scientific medicine will be sustained, in their true sense.

The special agreement made by the pharmacist is as follows:

"I, the undersigned pharmacist, having examined the resolutions adopted at recent meetings of conference between a committee of the Medico-Legal Society of Philadelphia and representative pharmacists, at the College of Pharmacy, presented in the accompanying circular of said committee to physicians and pharmacists, bearing date of December 10, 1880; and having also examined the fuller explanatory provisions for inter-professional reform embraced in said circular; in order to elevate the profession of pharmacy to a consistent pharmaceutical basis, and promote needful reform in the relations between physicians and druggists, I hereby agree to protect the public welfare and the province of the regular physician, as well as the interests of regular pharmacy and legitimate pharmaceutical manufacturing, by placing out of sight all patent and trade-mark medicine signs and medicines, refraining from distributing all patent nostrum almanacs and other forms of such advertisements, and discourage the sale of all preparations offered by patent and trade-mark pharmaceutical speculators: I also agree that neither myself nor my employees will renew any physician's prescription marked '*Do not Renew*,' or its equivalent: I also agree that in all cases where applicants for medical treatment can be referred to a regular physician, such applicants will not be prescribed for in any manner by either myself or my employees."

The physician's agreement is as follows:

"I, the undersigned physician, having examined the resolutions and explanations embraced in the circular aforesaid, hereby agree to promote legitimate pharmacy and the manufacture of regular pharmaceuticals, by withholding my professional patronage from all patent and trade-mark pharmaceuticals, so far as I am able to comprehend the same, *and will throw the weight of my patronage and influence in favor of those pharmacists* who comply with the request of the regular medical profession regarding the correction

of the irregularities and abuses above specified in agreement of druggists, and will use the proposed list as my guide in selecting pharmacists worthy of professional and public confidence."

EMPIRICISM CONFIRMED BY SCIENCE.—To any one interested in medical archæological lore, a rich mine of interesting material exists in the numerous Gaelic manuscripts still existing in the Advocates' Library, Edinburgh, and elsewhere. These manuscripts are written in Latin, and by practitioners educated for the most part on the Continent, and ignorant, we may tell the vainglorious Southron, of the English language. It is interesting to note, possibly as a survival from our Gaelic physicians, that a popular cure for dyspepsia, not long ago, in the Highlands, consisted in the lining membrane of the gizzard of the cock, dried and powdered. Is this a case of the confirmation by science of empirical experience and observation?—*Medical Press and Circular.*

A MOVABLE ATLAS OF THE MALE ORGANS OF GENERATION AND REPRODUCTION.—This is now one of the well-known Atlas series, by Dr. Witkowski, and published in London by Baillière, Tindall & Cox. By means of a series of movable colored layers of paper, it shows the various structures which make up the male organs and the perineum. The view thus given is a very good one, and is quite sufficient for the student who happens to be reading anatomy when dissection is over. The Atlas will be found most useful for demonstration of parts during clinical instruction. The accompanying letter-press, translated by Dr. Campbell Black, contains some curious information, and is written in a very pleasant style; but it is not as full and definite either in physiology or in anatomy as would suit any student preparing for examination.—*Medical Press and Circular.*

EXCISION OF THE STOMACH.—Prof. Billroth, of Vienna (*Lancet*, vol. i., 1881, p. 268), recently excised about six inches of the greater curvature of the stomach, including the pylorus, for infiltrating carcinoma. The operation lasted an hour and a half. There were extensive adhesions to the omentum and colon. Fifty silk sutures were used to unite the duodenum and the remaining portion of the stomach. A week after the operation the sutures were removed from the external wound, which had united without reaction. The patient was doing well, and was able to take coffee, tea, and other light nourishment. This is the second operation of the kind. The first, by Prof. Péan, resulted fatally in four days.

PHOSPHIDE OF ZINC IN LOCOMOTOR ATAXY.—Dr. Hastings Burroughs (*Medical Press and Circular*, February 9, 1881) gives this drug in one-eighth grain pills,—one a day for a week, and then two daily, and so on up to five. He has treated his cases successfully thus far.

DR. LAURENCE TURNBULL, who is an acknowledged authority upon the ear and its affections, has just had published, through J. B. Lippincott & Co., the third edition of his monograph on Defective Hearing and the Hygiene of the Ear. Some of the subjects treated of are nervous symptoms, tinnitus aurium, etc., with a portion devoted to the home instruction of the deaf.

NOTES AND QUERIES.

PHILADELPHIA, March 4, 1881.

EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I have just received from Dr. R. L. Sibbet, of Carlisle, Chairman of the Committee on Medical Legislation of the State Medical Society, the following copy of a note from a member of the House of Representatives, in regard to the bill to regulate the practice of medicine now before that body:

HARRISBURG, March 2, 1881.

MY DEAR DR. SIBBET,—Our bill has been read a second time, after a somewhat stormy debate, and has been ordered to be transcribed to third reading; vote, one hundred and thirty-one to five.

Yours truly,

W. B. ROBERTS.

The large majority thus indicated affords reasonable ground for the expectation that if physicians throughout the State will unite in urging upon their acquaintances in the Legislature the importance of the act, the present session will see it a law. I communicate this in the hope that some of the large number whom your journal reaches may be stimulated to use their personal efforts in its behalf.

Yours very truly,

BENJAMIN LEE,
Secretary of Committee on Medical Legislation, Medical Society of the State of Pennsylvania.

AT a meeting of the New York Academy of Medicine, held January 20, 1881, the following resolution was adopted:

Resolved,—That a committee be appointed by the President to investigate the extent to which leprosy prevails in the United States.

The President appointed as such committee Drs. H. G. Piffard, F. R. Sturgis, and G. H. Fox.

The committee are desirous of ascertaining the actual number of lepers in this country at the present time, and to that end respectfully request any physician who may know of the existence of a case in his neighborhood to communicate the fact to the chairman of the committee, at No. 10 West 35th Street, New York.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM FEBRUARY 20 TO MARCH 5, 1881.

MEACHAM, FRANK, CAPTAIN AND ASSISTANT-SURGEON.—As soon as able to travel, to report in person at Department Headquarters, for assignment to a station. S. O. 32, Department of the East, February 19, 1881.

GIRARD, J. B., CAPTAIN AND ASSISTANT-SURGEON.—In obedience to S. O. 14, c. s., A. G. O., relieved from duty in Department of Texas. S. O. 20, Department of Texas, January 29, 1881.

GARDINER, J. DE B. W., CAPTAIN AND ASSISTANT-SURGEON.—Granted leave of absence for one month, to take effect when relieved by a medical officer, with permission to apply for an extension of five months. S. O. 16, Department of Arizona, February 8, 1881.

WILLIAM H. ARTHUR, GEORGE E. BUSHNELL, H. P. BERMINGHAM, and M. C. WYETH.—Appointed Assistant-Surgeons, United States Army, to rank from February 18, 1881.

PHILADELPHIA, MARCH 26, 1881.

ORIGINAL LECTURES.

CLINICAL LECTURE ON ARSENICAL PARALYSIS.

Delivered at the Pennsylvania Hospital

BY J. M. DA COSTA, M.D.

Reported by FRANK WOODBURY, M.D.

GENTLEMEN,—The man whom you now see is a very different patient from the man who entered the hospital some time since. His condition has greatly changed for the better; indeed, even his features wear a different expression: so that while I am reading the clinical history you will be obliged to make a certain allowance in order to appreciate the application of the notes to the case before you. I mention this that you will understand that the comparison which you will thus make mentally between the case and the record may not suggest any exaggeration or misstatement in the record, kept since the date of his admission, September 13, 1880. While some of the features then existing are still obvious, others are at present too slight to yield any evidence in regard to the cause or form of disease from which he has suffered. The patient's name is Andrew B.; he is 19 years of age. When he entered the ward he was in such an unfavorable mental condition that it was impossible to gain from him any trustworthy history; indeed, the notes say that he was for a time completely out of his mind; but, partly from his own statements and chiefly from what could be gathered from his friends, we learned that he had had gonorrhœa, and that he also had contracted syphilis about a year before admission. This, however, had not been followed by secondary symptoms, and in the main he seems to have been a healthy person.

From his statements it also appeared that about three months before entering the hospital he began dosing himself with arsenic with a view of improving his appearance, having somewhere learned of this practice among the Styrian peasants. He commenced by taking "small pinches" of arsenic,—arsenious acid, I presume,—and, increasing the dose gradually, he got up to about three or four pinches in the twenty-four hours. This had been going on for three or four months before his present train of symptoms appeared. For the last ten days before he came here he had been complaining first of sore throat, and, later, of abdominal pain, vomiting, and diarrhœa; he also had headache, bleeding at the nose, some cough, and decided palpitation of the heart. Notice these symptoms. You will say, How like the beginning of typhoid fever! So they were; and, what makes the resemblance greater, on admission he was even delirious. His temperature was 102½° (axilla), his respiration 26, and the pulse 130 to the minute. Everything indicated a fever of low type,—fever, mental wandering, dry skin, prostration. But what arrested our attention at once was what is stated very specially in the note, "his face and legs were œdematous." His tongue was coated; we also found upon examination that he had a slight right-sided pneumonia and a moderate amount of erythematous eruption or roseola upon the chest and abdomen. The urine was examined the morning after admission, and found to be normal. He was kept quiet in bed, and placed on a diet consisting largely of milk; his medical treatment was an ordinary fever-mixture and effervescing draught, with a little lead and opium for his diarrhœa, which was soon controlled. He rapidly got better; but it was found on September 30, notwithstanding the evident improvement in his acute symptoms, that he could not stand upon his legs; his mind too, was not in a healthy condition.

Let us now glance over this history. Here is a man who comes into the hospital with fever, some pneumonia, diarrhœa, and in short, in many respects, the symptoms of typhoid fever. As he recovers it is found that he cannot stand up, his legs will not support him; but it is also found that he can move his legs, although with reduced force, when he is lying down. We subsequently learn from his brother that he had an epileptic convulsion on the day before he came in. Another important point that I want you to remember is that the sensibility was good, indeed it appeared exalted; and he complained of a sense of formication, and frequently of aching pains in the muscles. He was very sensitive to tickling, and near the ankle he had some numbness,—perhaps from pressure upon

his heels. In making the examinations he cried and complained so much when sensation was being tested that we were, after several efforts, obliged to content ourselves with the general result above stated. He had at that time frequent jerkings of the muscles of the legs, and powerful reflex movements were easily excited. With some reference doubtless to the syphilitic history (I was not in charge of the wards at that time), he was placed upon sirop Gibert, which you recognize as an antisyphilitic remedy, consisting principally of iodide of potassium and biniodide of mercury. I mention these points somewhat in detail in order that you may know what the symptoms were, and what was the treatment, the better to understand the subsequent course of the case. But very little change took place under this treatment: indeed, his nutrition became worse, he was emaciated, almost idiotic in mind, rambling, incoherent, having illusions which greatly annoyed him, and made him so noisy at night that he much disturbed the other patients; he was very irritable and whining often during the day.

It was in this condition that I saw him when I first took charge of the ward. He was in a curious mental state, which I may sum up as in the main hysterical; there was great fretfulness, with frequent exhibitions of temper, alternating with spells of crying; he had to be fed like a child; he was restless, slept poorly at night, and was unable to stand; he told us that he had some pains in the legs on motion.

Now, we tested the legs, and found that the soles of the feet were very sensitive to the touch, and reflex movements increased. There was absent patellar tendon reflex, but he complained a great deal when the tendon was struck. The nails of the toes were growing, although there was decided muscular atrophy in the thighs as well as in the legs. The electro-muscular contractility was not lost to the faradic current; the rectus and sartorius contracted, but it required a strong current to make them contract; the sensibility to the current was poor in the legs, but better in the thighs. Ordinary tactile sensibility was not impaired; it seemed, indeed, that there was a certain degree of hyperæsthesia. Although the muscles were wasted, they did not yield the reaction of degeneration. The atrophy was about equal on both sides, and the circumference over the largest portion of the calf was only nine inches. The arms were well developed. As you notice, his frame is rather large.

Gentlemen, I placed our patient upon very large doses of iodide of potassium, with the most marked result. He has grown fat, his appetite is good, he can feed himself now, and often asks for more; his mind is much better; indeed, he is quite rational. His eye-ground, examined with the ophthalmoscope, shows a great deal of active congestion, a neuro-retinitis, but no choking of the disk nor atrophic change in the optic nerve. He only has a slight headache occasionally. He has lost his curious peevishness and hysterical manifestations; he sleeps well at night. In every respect, mentally and physically, he has improved, and in his features markedly so.

But what about the legs? Their condition you see for yourselves. You notice a state of affairs that still exists, though to a less degree than a few months ago; they have dwindled. There has been, however, a gain of more than an inch in circumference under the treatment. Your attention is called to the curious position of the legs and feet: owing to paresis of the flexors the feet are very much extended, so as to be almost in a line with the legs. He moves the legs and kicks when requested, although feebly; you see that muscular power is still impaired, though when lying down, as he is now, there is more power than when he tries to stand, which he is still unable to do without assistance. I do not think that there was ever entire loss of muscular power, but he has certainly regained much of it, particularly within the last three or four weeks. Notice the nails, which are still growing; they have emerged now some distance and are claw-like. Notice also the capillary congestion of the skin around the joints, and its thin polished surface as though its nutrition were affected. Sensation in the soles of the feet is good, and a prick with a pin produces at once reflex movements: he jerks away the leg instantly. Sensation of the leg itself is good; in the thigh it is very good. Indeed, at one time, as I have already told you, he seemed to be over-sensitive to touch, but on account of his mental condition it was difficult to find out just what he felt, and I have some doubts about his sensation, as he complained very much when he was disturbed. We may conclude from our examination

that still there is incomplete loss of power, without impairment of sensibility, in both lower extremities.

You saw that with an ordinary faradic current there was no contraction of the recti muscles. But when we used a very strong current the recti contracted, and so did the sartorii; that was with the slowly-interrupted current,—with a perceptible interval between the shocks. With the usual current of moderate strength there was no action. Using the same strength of current in the muscles of the leg, good contraction is produced in the gastrocnemius; in the flexors, where there is the greatest loss of power, there is only the merest quiver of the muscle even with a very strong induced current. Very much the same state of things exists in the left leg as in the right: there is scarcely any appreciable difference. But even when no movement is produced the man says that he feels the current. To complete the examination, I will add that the grasp of the right hand is deficient; the left also has a feeble grasp, but not quite so feeble as the right. The skin of the hands is soft; they are perspiring a great deal. The muscles of the upper extremities now respond to the current, although at one time they did so very feebly. They have gained in electro-muscular contractility, though never has it been lost in them to the same degree as in the legs; they have decidedly gained in power of voluntary movement, for a few months ago, you remember, he was unable to feed himself. The nails here are growing too, just as in the lower limbs. There is at present no heart or lung complication; an anæmic murmur which formerly existed has passed away; the heart is rather irritable and quick, but presents none of the signs of disease. The temperature now is normal; the urine is normal. The temperature became normal soon after the acute symptoms of the first days of admission passed away, yet until quite lately there have been occasionally, and seemingly without cause, sudden rises to 101° or 102°, lasting for a day or two,—on one occasion for a week; the highest temperature reached in these irregular rises was 103.5°, on the 25th of October.

Now, what is the explanation and significance of these symptoms? Here we have one of those rare cases of marked paralysis following chronic arsenical poisoning. As the case is so rare, I propose, first, to make out a more definite diagnosis, determining what in my judgment this form of paralysis here present really is; and, secondly, I shall offer some general remarks upon paralysis following arsenic.

What form of paralysis is this? We can say truly that it has been chiefly a spinal paralysis. I do not mean to say that there were no brain-symptoms, but the form of the paralysis has been what we find especially in spinal lesions. It is, I think, a spinal palsy. Next let us consider what variety of spinal lesion exists. The parts involved in the paralysis are, as you have seen, the four extremities; the arms, as well as the legs, have been affected, though the legs have borne the brunt of the disease. We must, I think, locate the lesion high up in the cord, or we must admit that it is general and extends throughout its length. From a review of the examination, we are forced to the opinion that the disease is a diffused lesion rather than a local one. What structure of the cord has suffered the greatest injury? Here I must allude to the more minute knowledge of nerve-structure and spinal disorders and some of the finer points in nerve pathology to which attention has only been comparatively recently attracted by the investigations of Erb, Charcot, Althaus, Seguin, and others. There are forms of spinal paralysis pre-eminently marked by progressive muscular atrophy, defective nutrition, and defective electro-muscular contractility,—defective rather than entirely lost: indeed, it is maintained by Erb that when the muscles fail to respond to the induced current they may even act more promptly to the galvanic current and with a weaker current than in health. Paresis is marked, wasting of the limbs is marked, and nutritive changes in the skin are marked, while sensibility is preserved; and many of these symptoms, as in acute poliomyelitis, come on acutely with headache and fever, and the paralysis rapidly reaches its highest degree. The muscular wasting becomes very marked; so it is in the lateral amyotrophic sclerosis of Charcot; and the nutritive changes, in addition to the palsy, bespeak in either case, though from a different cause, a certain alteration, degenerative in character, in the ganglion-cells of the anterior horns of the gray matter of the cord, which have so powerful an influence on nutrition. Now, when you look at the clinical features of the case before us, you see how closely they re-

semble those of a spinal paralysis with involvement of the trophic spinal centres,—how in many respects they are like those of acute anterior poliomyelitis.

I think I have now proved to you what kind of paralysis it is, and what is the seat of the marked lesions of the spinal cord here produced by arsenical poisoning. You see that it is chiefly in the ganglion-cells of the anterior cornua, and, judging from the marked motor affection, we know that the disorder has also diffused itself over the anterior or antero-lateral columns. The nature of the lesion is, I think, irritative or inflammatory, attacking, very likely, connective tissue as well as nerve-tissue.

The case that I have been expounding to you is, I believe, an important one from the point of view that it will give us a rather more accurate insight into the nature of arsenical paralysis than we have hitherto possessed. That arsenic will produce palsies, that these may happen without marked cerebral symptoms, that in certain cases atrophy of the muscles occurs, has been long known, and you will find in medical literature a number of instances reported. But, while these establish this fact, they are mostly cases of old observers,—as in the group brought together by Christison,—and so placed on record as to be next to valueless from the point of view of the requirements of modern scientific diagnosis and pathology. Still, I think that any one who will take the trouble of analyzing the cases, as I have done with a number, will at least be struck with this point, which indeed I do not hesitate to formulize into a law,—that arsenical poisoning, whether partial or general, is pre-eminently, I may say almost invariably, a spinal paralysis. In some instances it seems to affect a special nerve-tract at its origin, but in most instances the lesion is more diffused.

Now, as to the part of the spinal cord particularly involved, it is not always the same. The observations brought together by Jaccoud in which violent and diffuse neuralgias are mentioned forbid us to doubt that the posterior roots of the spinal nerves are sometimes implicated. But, reviewing the whole field, I have been impressed with the frequent absence of sensory phenomena; and I believe I am right in affirming that the poison exerts its influence particularly on the anterior or antero-lateral columns. I will go still further. In analyzing the cases, I have been struck with the number of instances of muscular atrophy terminating in fair recoveries; and, placing these together and examining them in the light of our modern knowledge of spinal affections, and bringing them in connection with this most striking case that we have been studying, I affirm that frequently the great ganglion-cells of the anterior cornua are involved, producing lesions similar to those of anterior poliomyelitis.

As bearing upon the subject, I will mention that in some very interesting researches in the September number of the *Archives de Physiologie* for 1875 a Russian physician, Scolosuboff, alludes to paralysis with muscular atrophy having been met with by him a number of times in the chronic arsenical poisoning which he states to be very common in Russia. Unfortunately, he gives no particulars and no clinical data to elucidate the matter; but, from an experimental point of view, and as aiding us in understanding the mode in which arsenic acts on the nervous system, his researches are very valuable, and may, I think, be most advantageously made use of in our argument. In animals slowly poisoned with arsenic, even where paralysis was produced, arsenic was found only in very small quantities in the muscles, while it was detected in very large quantities in the spinal cord and in the brain,—in amounts not only much larger there than in the muscles, but also much larger than in the liver. In the most conclusive experiment cited, the proportion of arsenic was as 1 in muscle to 36.5 in brain and 37.3 in spinal cord. In the more acute instances of poisoning the arsenic was first found in considerable amounts in the brain, and subsequently it accumulated rapidly in the spinal cord. The nervous symptoms of arsenic-poisoning, including the paralysis, we may, then, fairly infer are due to the localization of the arsenic in the nervous centres. The delirium, the epileptic convulsions, the headache, of the earlier stages bespeak plainly the brain-affection; the palsy, which is generally double-sided and not an early symptom, shows the presence of arsenic and the subsequent changes in the spinal cord, and is not caused, it is evident, by direct action of the arsenic upon the muscle.

Now apply these results to the solution of the case before us, and see how easily most of its symptoms are explained. Here was delirium at first, great mental

perturbation subsequently, a deeply-injected eye-ground: the arsenic was acting upon his brain. Indeed, there can be no doubt, if I read this clinical history correctly, that its action upon the brain preceded its action upon the extremities. He entered the hospital in this curious condition; but the resident physician informs me that he certainly was able to walk on that day, and it was not noticed until afterwards that he could not stand,—arsenic acting upon the spinal cord just as in the experiments upon dogs, where the spinal cord was found in a state of congestion, with more or less inflammation. But what portion of the spinal cord is principally invaded? This—which I have already explained to you will vary according to where the arsenic chiefly accumulates and leads to secondary changes—is solved by the clinical investigation. Here marked interference with nutrition showed that the disturbance must have been chiefly in the gray matter of the anterior cornua, where are situated the large ganglion-cells. Thus, applying the results of recent experimental investigation to the clinical history of the case, we have the pathological conditions unfolded, or at least made almost certain.

In concluding the review of the symptoms and the causes of the case, it may be of interest to you to know that we have used the muscle-trocar of Dr. Hart upon these wasted muscles of the legs, and found that they had undergone considerable degenerative change. Some of the fibres showed fat-globules, but the most of them had rather a waxy appearance. So far as I know, these microscopic changes have not in cases of this kind before been demonstrated. I will therefore describe them more in detail. The tissue was pale. The changes noticed in the muscular fibre were those of simple atrophy, reduction in size with faintness of striation, rather than fatty degeneration; there was also a state of things akin to waxy change, the fibres were found converted into rounded lumps, and broken up transversely, their corners rounded off, resembling the waxy degeneration sometimes found in the muscles of typhoid-fever patients. They were not, however, homogeneous vitreous masses, but clouded, and granular for the most part; yet fragments were seen which were highly refractive and lustrous. There was some fatty atrophy of the connective tissue, and here and there hyperplastic changes, not only relative but absolute.

You see the remarkable improvement in the muscular system which is taking place, and you can believe me that the mind also has improved: so that we are now able to assume that the disorder of the spinal cord, like that of the brain, will soon pass away; at least it will do so to a very great extent.

It only remains to speak of the treatment, and what remedy has been especially serviceable. Iodide of potassium in large doses, in my opinion, has been the principal agent in effecting the beneficial change. Iodide of potassium is not only very effective in eliminating mineral salts from the system, but at the same time it favors better nutrition after morbid processes. It is used in various forms of metallic poisoning, and some of its good effects in this case I attribute to its power of elimination. But I cannot think that it has acted this part alone: it has also been a great modifier of tissue-change, and especially of pathological change. However this may be, we cannot doubt the result: there has been great improvement. You could hardly believe the patient to be the same person if you had seen him, as we did, a few months ago, so emaciated and almost idiotic. He has been taking twenty grains of the potassium salt three times a day, which comparatively large dose he has borne well and fattened under it. Previous to its administration, while mainly on general tonics, he was not gaining. He has good diet, and to the affected muscles the faradic current is applied every second day.

You may ask, Will complete recovery take place here? In the brain, yes. I do not believe that there will be any alteration or serious impairment of the mental powers; the brain-cells will be restored to their normal functions. Will he recover fully the use of his limbs? In the upper extremities, yes; but in the lower extremities I scarcely think that he will ever do so entirely. He may walk about, even without crutches, but I hardly believe that he will recover the use of these wasted flexor muscles of the foot.

Judging by the improvement of the last month, he will come very near to a recovery; but he will never be entirely a healthy man, as he was before he began the habit of taking arsenic in pinches for its beautifying effect.

March 7.—I add this note as to his present state. His general condition is good; he has continued to gain in flesh, weighs 132 pounds. He can now read with the aid of the same glasses that he used before he fell ill; has no headache, only occasional vertigo; the muscular system is well developed in the upper half of body; the legs are gaining in size,—left calf measures 11½ inches, right, 11¼ inches. He can walk with a cane, and go up- and down-stairs by himself. The appetite and digestion are good. The skin is in good condition, except in the feet, where there is some erythema and scaling; around the toe-nails there is superficial ulceration. He sleeps well at night, and is in good spirits.

ORIGINAL COMMUNICATIONS.

THE PHYSIOLOGY OF CLIMATE, SEASON, AND ORDINARY WEATHER-CHANGES.

BY ALEXANDER RATTRAY, M.D.,
San Francisco.

(Continued from page 369.)

THE PHYSIOLOGY OF SEASON.

IN regions where spring, summer, autumn, and winter are well marked, and the annual thermometric range is considerable, the physiological changes induced by the rotation of the seasons correspond more or less with those caused by zonal change of climate. For example, Table IV., which epitomizes some observations made in San Francisco during 1878–79, proves that the spirometric capacity of the lungs rises from two hundred and forty to two hundred and sixty-seven cubic inches under an increase of 35° Fahr. in-doors.

TABLE IV.—TO CONTRAST WINTER AND SUMMER SPIROMETRIC CAPACITY.

	Winter.		Summer.		Difference.	
	Temperature—Air. Fahr.	Spirometer. Cubic inches.	Temperature—Air. Fahr.	Spirometer. Cubic inches.	Temperature—Air. Fahr.	Spirometer. Cubic inches.
Lowest	51°	240	66°	243	15°	3
Highest	75°	252	86°	267	11°	15
Average	65°	248	70.5°	259	5.5°	11
Range	...	...	35°	27		

Table V. further shows that the number (and, doubtless, the depth) of the respirations are diminished.

TABLE V.—TO CONTRAST THE NUMBER OF RESPIRATIONS PER MINUTE, SUMMER AND WINTER.

	Winter.		Summer.		Difference.	
	Temperature—Air. Fahr.	Respirations per minute.	Temperature—Air. Fahr.	Respirations per minute.	Increase of Temp. Fahr.	Reduction of Resp.—Summer.
Lowest	58°	13.5	65°	12	7°	1.5
Highest	75°	16.5	86°	16	11°	0.5
Average	66°	14.	70.6°	14	4.6°	0.5

Tables IV. and V. together clearly indicate a reduced respiratory function and pulmonary vascularity during summer, similar to what occurs during tropic heat. Again, Table VI. shows that the temperature of the body (in-doors and under the tongue) rises perceptibly in summer,—namely, from 99.62° (average winter temperature) to 100.16° Fahr. (average summer temperature),—a fact which corresponds with and corroborates the rise observed in the tropics.

TABLE VI.—TO COMPARE THE SUMMER AND WINTER TEMPERATURE OF THE BODY.

	Temperature. Winter.		Temperature. Summer.		Difference in summer.	
	Air.	Body.	Air.	Body.	Air.	Body.
Lowest	58°	98.75°	65°	99 50°	7°	0.75°
Highest	75°	100.25°	86°	100 50°	11°	0.25°
Average	66°	99.62°	70.6°	100.16°	4.6°	0.54°

Again, Table VII. shows that the pulse beats less frequently (and, perhaps, less forcibly) in summer. This corroborates former observations for the tropics.

TABLE VII.—TO COMPARE THE SUMMER AND WINTER PULSE.

	Pulse. Winter.	Pulse. Summer.	Reduction in summer.
Lowest	68	72	
Highest	100	86	
Average	84.2	83 9	0.3

While these phenomena are in progress there is, doubtless, a slight change in the hepatic secretion also. The perspiration is likewise notably increased, and the urine perceptibly diminished.

On the return of winter, results of the very opposite nature ensue, corresponding

to those which occur on moving from tropical to temperate regions; and, although in the climate of San Francisco, where the thermometer seldom falls so far as, and never goes much below, the freezing-point, and the annual range of temperature is comparatively small, these evidences of functional change are not so great as they are in other parts of the Pacific slope, and especially in the Middle and Eastern States, where the summer heat and the winter cold are much greater, still, they are sufficiently marked to be both interesting and important. In the latter regions, where the thermometric range is considerable, these physiological changes are correspondingly increased, and more like those induced by climate. And there can be little doubt that both in their cause and sequence these seasonal phenomena are not only identical with the greater ones induced by zonal change of climate, but also that they sometimes even rival them in extent and importance. In summer there is an increase in the cutaneous vascularity and function, and a reduction in those of the lungs, kidneys, and other internal organs and parts, while during winter the internal organs become turgid and functionally active at the expense of the external ones.

THE PHYSIOLOGY OF ORDINARY WEATHER-CHANGES.

The frequent, often considerable and sudden, diurnal weather-variations, which occur everywhere and mark one day from another, night from day, and even one part of the day or the night from another (for example, mid-day or midnight from morning and evening), induce physiological phenomena in every respect like those caused by climate and season. On a warm day, or during a succession of warm days, the pulse (*cæteris paribus*) becomes slower and feebler; the bodily temperature rises somewhat; the perspiration increases; and if the ingesta, exercise, and repose were alike, the urine would be less in quantity by day than by night, owing to the higher temperature. As it is, it is greatest then, because these influences more than counterbalance the effect of heat. The respiratory function is also least active during the *warm* hours of the day. This is shown indirectly by the spirometric capacity being greatest then. For example, it fell from two hundred and sixty-one cubic inches at 3 P.M. (temperature 73° Fahr.) to two hundred and fifty-two cubic inches at 11 P.M. (temperature 68° Fahr.) It also rises and falls all the year round, with the difference between one day's temperature and another. Thus, in summer, at 3 P.M. (temperature 68° Fahr.) it was two hundred and fifty-two cubic inches, whereas next day (temperature 74° Fahr.) it had risen to two hundred and sixty-one cubic inches, and the following day (temperature 86° Fahr.) to two hundred and sixty-seven cubic inches. In winter there is a similar rise and fall with the temperature. Thus, one day at 3 P.M. (temperature 68° Fahr.) it was two hundred and forty-nine cubic inches, next day (temperature 58° Fahr.) it fell to two hundred and forty cubic inches; on the following day (temperature 64° Fahr.) it rose to two hundred and fifty-two cubic inches. Doubtless the number of respirations and their depth are also diminished. And there can be little doubt that these physiological changes have the same cause, although less pronounced, partly from the slighter and shorter difference in the temperature, and partly from their being more affected than the climatic and the seasonal phenomena by such disturbing agencies as food, exercise, clothing, artificial warmth, etc., which sometimes counterbalance and even entirely obliterate them. Notwithstanding this, however, when the body is put under the strict conditions necessary for experimental research, or when the diurnal weather-changes are very marked (as they often are in some seasons and places), and the difference in the temperature is great, especially when the latter rises to tropical heat and sub-arctic cold, the physiological phenomena now mentioned are sometimes as great and important as those resulting from climate and season. Moreover, even when not so great as the climatic and the seasonal changes, these diurnal ones are often more trying and dangerous from their suddenness; and *many and severe diseases result therefrom in all latitudes*, especially when weak organs predispose, and where the diurnal range of temperature is great and trying.

Similar but minor phenomena likewise follow subjection to *artificial climates*. Thus, on moving from the cold external air into the heated atmosphere of a room, hall, church, etc., the bodily temperature, skin-function, and spirometric capacity of the lungs soon increase, while the number

of respirations diminish, thereby indicating a diminished respiratory function. For example, on going from the external air (temperature 30° Fahr.) into a room (temperature 57° Fahr.), an individual's respirations fell from 17.5 to 15.8 per minute, and the spirometric capacity rose from two hundred and thirty to two hundred and forty-two cubic inches. So also an individual's temperature (under tongue) rose from 97½° to 98½° Fahr. on going from a temperature of 52° to one of 63° Fahr. Phenomena of an exactly reverse nature follow an opposite change of temperature. When the difference in temperature is greater than in the above instances, the resulting phenomena are necessarily more important; and, though usually not so great as those induced by climate or season, these changes are frequently more sudden and correspondingly trying to the implicated organs, especially when the surface is unusually chilled by imperfect clothing. Unquestionably many inflammatory diseases of internal organs, especially the lungs, originate thus.

Similar but milder phenomena follow subjection to heat or cold otherwise induced, as, for example, by warm or insufficient *clothing*. The former not only increases the temperature and exhalation from the skin, but also augments the spirometric capacity by from ten to fifteen cubic inches, thereby indicating reduced lung-function. Thin clothing does the reverse, —chills the surface and congests internal organs. *Exercise* first lessens and afterwards increases the spirometric capacity. Thus, at 3 P.M. (temperature 66° Fahr.) a spirometric capacity was two hundred and sixty-one cubic inches; at 4 P.M., after a smart walk (temperature 66° Fahr.), it was only two hundred and forty-three cubic inches, showing that the lungs were congested and increased in physiological activity; but shortly after, when perspiration appeared, the spirometric capacity soon rose to the old standard, the skin having come to the aid of the lungs and induced what is known as the "second wind." So the hot-water bath increases the temperature in health (*e.g.*, from 97⅓° to 98½°), as well as the spirometric capacity of the lungs. As is well known, the cold bath has an opposite effect,—first cools the surface, and then the body generally, depleting the cutaneous capillaries and congesting internal organs.

These numerous and widely-dissimilar vital phenomena, arising from apparently occult factors either in climate, season, or ordinary weather-changes, invariably recur when the conditions are identical; and, with our present knowledge, it is now possible to explain and correlate them, define their extent, and point out their pathological, etiological, hygienic, and therapeutic bearings. Individually they are links of one chain; and the following table, in which the scattered, complex, and apparently disconnected data are grouped together, will go far to prove their relationship, collective association, and mutual functional bearing, ordinary or vicarious.

		+ indicates increased and — diminished function.	
		Change from temperate zone to tropics; winter to summer; night to day.	Change from tropics to temperate zone; summer to winter; day to night.
External organs	Skin function	+	—
	Skin temperature	+	—
Internal organs	Lungs	—	+
	Kidneys	—	+
	Liver	—	+
	Heart	—	+

Seeing that an increase of function—no matter whether that may be secretion or not—is equivalent to and aided, if not caused, by an increase in the vascularity of the involved organ, while a diminished function indicates a corresponding vascular depletion, it follows that the above physiological changes are equivalent to an *increased or diminished blood-supply;* and, following up this clue, it will next be noticed, from Table VIII., that an increased function and vascularity of certain organs invariably accompany an increase in other organs and a simultaneous decrease in certain others. Moreover, this increased or diminished vascularity and function occur mainly in organs whose functions are not only special, but also vicarious,—viz., the lungs, kidneys, skin, and liver,—that is, in the four great depurating organs; so that the change involves chiefly the excretion of carbon, water, and perhaps nitrogen.

It will also be observed that the organs thus physiologically grouped in vascularity and function, either on the side of increase

or of decrease, are the *internal* and the *external*, the *external* being most vascular and active in *high* temperatures, with a corresponding decrease in internal organs, while the *internal* are most active and hyperæmic in *cold* atmospheres, at the expense of the correspondingly depleted and inactive external organs. In short, change of climate, season, and such weather-variations as involve an increase of *heat* usher in two different sets of phenomena,—namely, an increased turgescence and functional activity of external organs and parts, with a diminished turgescence and functional activity of internal ones; while opposite changes that involve an increase of cold likewise induce two sets of changes the very reverse of those caused under the previous circumstances.

The only theory capable of satisfactorily explaining and correlating these apparently involved and contradictory physiological phenomena is that they are, individually and collectively, due to what may be termed the *climatic* law of the circulation, the main feature in which consists in a change, redistribution, readjustment, or diversion in the blood-current, which in *warm* atmospheres tends more towards *external* organs—that is, to the skin, cutaneous glands, etc.—and necessarily less towards internal ones. In *cold* temperatures the reverse follows, the lungs, kidneys, liver, and other internal and circumosseous organs and parts being then congested and functionally excited at the expense of external or peripheral ones. The great base fact thus is that these phenomena are merely the outward and visible expression and result of this great and important law, that *heat* congests *external* organs, thus depleting internal ones, while *cold* does the reverse, and congests *internal* organs by depleting external ones. Doubtless the entire volume of the blood and every organ and part of the body participates in these changes, and becomes either anæmic or hyperæmic, according to its position and relations. The extent of the resulting phenomena shows not only how much these factors—climate, season, and weather—influence individual parts and the body generally, but also that they affect it more than any other agency to which it is exposed.

Although the body, both in its healthy and in its diseased states, is materially affected during climatic, seasonal, and weather changes by other meteorological influences, especially the amount of sunshine, humidity, barometric pressure, electricity, situation, physical condition and conformation of the country, chemical and physical purity of the air, etc., unquestionably the never-absent factors which have most to do, directly or indirectly, with the production of this diversion in the blood-current and the resulting physiological phenomena are *heat* and its reverse, or, rather, its absence,—*cold*. Both of these, moreover, are double factors, inasmuch as they involve not only the temperature of the *air*, but also, and primarily, that of the *body*, especially the cutaneous system.

Seeing that the highest temperature during these experiments was only 88° Fahr., and as the resulting physiological phenomena begin to manifest themselves long before the temperature of the air reaches that of the blood (98° Fahr.), or even the lower temperature of the skin,—say when the aërial temperature is 90°, 85°, or 80° Fahr., and even less,—it follows that they do not arise either from direct or radiated solar heat, nor, indeed (except indirectly), from the heat of the air at all, but from the withdrawal of the cold air, the effect of which kept the cutaneous temperature down, and the resulting slight increase in the surface caloric of the body. That the latter would soon rise considerably higher than it does but for the cooling produced by evaporation of the increased perspiration is proved by disease and the increased temperature of the skin when the perspiration is stopped. This slightly-increased cutaneous heat is, doubtless, the earliest of all the physiological results of increased aërial temperature, and the forerunner of the subsequent and major ones. An early sequel of this is hyperæmia of the cutaneous capillaries, induced partly by the direct sedative, relaxing, and dilating effect of heat on the vessels, in or near which the surface caloric is generated, and partly, and no doubt mainly, through the cutaneous nervous system.

Modern research is proving, step by step, that not only this but every organ, part, and even cell, every function and vital process, is, both individually and collectively, under the control of the nervous system. Luchsinger, Wood, Field, and Nawrocki have lately shown that the sweat-glands have definite nerve-fibres and

special nerve-centres situated probably in the medulla oblongata and spinalis. Stimulated by heat, the thermic nerves and centres, acting, doubtless, in concert with the sudorific centres and nerves, soon induce increased perspiration, the evaporation of which withdraws latent heat, and thus cools the surface, as the cold air previously did. Adamkiewicz has shown that external physical, and therefore internal or body, caloric is one of the stimuli which excite this secretion, and also that the activity of the secretion seems to stand in direct relation not only to the temperature of the air, but also to that of several parts of the body.* Experiment has also shown that the secretion of sweat is essentially independent of any changes in the general circulatory system, but is controlled by the nervous system, thus proving that perspiration is not a mere transudation, but the result of the excitation of special glandular cells by the stimulation of certain nerves, which act according to the varying wants of the system. On the other hand, on subjection to a cold or temperate atmosphere this acts as a stimulant and ultimate paralyzer of the sudorific nerves, and a direct contractor of the cutaneous capillaries, thereby checking the perspiratory function. Moreover, while these changes in the cutaneous system are in progress, either from heat or from cold, the nervous system is simultaneously increasing or decreasing the circulation and functional activity of other vicarious or independent organs, and at the same time adjusting and correlating them, and acting as a bond of union in keeping the whole in harmonious — that is, in healthy — action.

In taking a comprehensive view of the subject, the most important and, indeed, paramount physiological effect of heat, and that which causes a majority of the others, is thus a constantly-varying balance of the circulation, during which the vital tide-wave sways under cold more towards central or internal (cranial, thoracic, abdominal, pelvic, and circumosseous) organs and parts, and under heat more towards external or peripheral ones, the one becoming injected or turgid at the expense of the other. The necessary result of this frequent oscillation in the blood-current is a constant change, by way of increase or decrease, in the functions of the different organs thereby depleted or congested, especially the secretory ones. In short, the local vascular determinations or anæmiæ thus induced are the causes of the different climatic, seasonal, and weather physiological changes above described.

It also follows that, in the United States or elsewhere, the greater the thermometric range encountered, either from change of latitude, altitude, season, or local weather-variations, the greater are the physiological changes so induced, and the more important these are from both a hygienic and an etiological point of view; and equally apparent is it that in places where the thermic range is less these changes are correspondingly reduced in extent and medical significance.

These physiological facts bring into especial prominence the function and vascularity of the skin, that organ which in the tropics has to bear the brunt of this sanguineous tide-wave from internal parts, and the chilling of which in cold weather sends a corresponding tide-wave to congest internal organs. Medical men, familiar enough with the larger vessels of the circulation, are too apt to overlook or underrate the great extent and importance of the capillary system, especially that of the cutaneous surface, the organ in which the physiological changes now spoken of mainly originate, seeing that it is on the cutaneous nerves and capillaries that the heat or cold which induces them first acts. Internally the blood is massed together in bulk, whereas on the cutaneous surface it is minutely divided and spread out in a dense net-work of capillaries. These microscopic vessels are not only the largest in the body next to those of the medulla of the bones, varying from $\frac{1}{3500}$ to $\frac{1}{2000}$ inch in diameter, but are so thick-set that they are separated by interspaces only three or four times larger than the vessels. The great importance of the cutaneous capillary system will become more evident if we recollect the vast extent of the cutaneous surface and the many structures which this great emunctory includes. These vessels supply,—1st, the perspiratory *glands*, which (reckoning two thousand eight hundred to a square inch and two thousand five hundred square inches as the cutaneous surface of a man of ordinary size) gives about seven million glands, which is equal to one million seven hundred and fifty

* London Lancet, June 14, 1879, p. 852.

thousand inches, or twenty-eight miles, of tubing;* 2d, the tactile *papillæ*, which Sappey estimates at one hundred and fifty millions for the entire surface;† 3d, the cutaneous *lymphatics;* 4th, the numerous hair *follicles;* 5th, the sebaceous *glands;* 6th, the *corium* itself; 7th, the *fat clumps* beneath it; 8th, the subcutaneous *cellular tissue.* Another apparently trivial but correlatively significant fact,‡ which will show the importance of the capillary system and prove that the volume of blood which these are capable of receiving is much greater than usually supposed, is this, that the combined area of the smaller venous branches is greater than that of the main trunks, so that the venous system and its contents represent a cone, the *summit* or smallest part of which corresponds to the heart, and the *base* to the circumference of the body. The capillaries which intervene between the venous and arterial radicles are necessarily of still greater volume; and thus we may estimate that the proportion of the total blood of the body which these cutaneous capillaries receive is probably not far short of one-fourth, if not one-third, of the whole.§ These facts will show that as with the capillaries generally, by which the most important processes of the body, both of animal and of vegetable life, are carried on, so those of the skin really play a far more important rôle in the animal economy than the larger conduits. The cutaneous nerve-supply is equally bountiful. Some idea may thus be formed of the importance of this vasculo-nervous net-work, and the amount of blood which at all times circulates through the skin, and the quantity which may be withdrawn from the general blood-current of the interior and diverted skinward to congest the cutaneous capillaries by exposure to heat, or, on the other hand, returned so as to deplete it under the opposite influence of cold. For example, it has been shown that in 83° Fahr. the lung vascularity is diminished by 17.88 fluid-ounces through reduced respiratory function. This goes mainly to the cutaneous supply. To this add the 17½ per cent. derived from the kidneys, also the 0.15 per cent. from the liver, and a like percentage from other internal organs, the exact amount of which, for obvious reasons, cannot be given in figures, but which, nevertheless, goes to swell the blood circulating at or near the surface. The sum of this probably raises the *cutaneous* circulation by two or three pounds, that is, to a total of from nine to twelve pounds, instead of from seven to nine pounds, as before.

(To be continued.)

* Wilson. Krause reckons the sudoriparous glands at two million three hundred and eighty-one thousand two hundred and forty-eight in number (Kirkes).

† Nouveau Dictionnaire de Médecine et Chirurgie, tome xxvi, pour 1878. ‡ Gray's Anatomy, p. 535.

§ The total blood in the body is reckoned at one-fifth of the weight,—*e.g.*, at twenty-eight pounds in one hundred and forty (Kirkes).

OBSERVATIONS UPON RÖTHELN.

BY LOUIS A. DUHRING, M.D.,

Professor of Skin Diseases in the Hospital of the University of Pennsylvania.

WITHIN the past six weeks a number of cases of rötheln, or so-called "German measles," have come directly or indirectly to my notice. On several occasions I have been called upon to give an opinion concerning the eruption, the nature of which had not seemed clear to the gentlemen in attendance. In all of these cases the diagnosis proved to be rötheln. From the fact, therefore, that difficulty is sometimes experienced in recognizing the affection, and for the reason that the nature of the disease is not thoroughly understood, I beg to present the notes of several cases which have been recently under my observation. I shall also refer to some interesting data communicated to me through the kindness of friends. The first case that I shall give may be regarded as typical of the affection and of the efflorescence in particular.

I was asked to see a young lady, twenty years of age, whom I had a short time before attended for an attack of herpes iris. She was apparently in good general health. The evening before she had complained of stiffness of the neck and slight swelling of the cervical glands. Simultaneously there appeared a copious, superficial, erythematous eruption, occupying the neck, chest, and back. There were no febrile symptoms, nor was there even malaise. The pulse and temperature were normal. There was no sore throat, erythema of the fauces, cough, or coryza, but there was very slight suffusion of the eyes. This symptom, however, was not marked enough to be appreciable to the patient. She felt perfectly well.

Upon examination, marked engorgement

of the cervical and post-cervical lymphatic glands was found to exist. A half-dozen of the glands could be readily detected in passing the hand over the integument, enlarged to the size of small almonds. The eruption was now general. It was, however, most pronounced about the chest, back, arms, and thighs, and faded towards the hands and feet. It was multiform in character, and consisted of more or less confluent, disseminated, ill-defined, pale-red or rosy, punctate and small split-pea sized faintly defined macules. In some localities, as about the forehead, some of the lesions were slightly elevated, producing a somewhat roughened state of the skin. The punctate lesions, the size of small pin-heads, were seen to best advantage over the back. The larger lesions were very indistinct in outline, and were irregular in shape and of variable size. They were all without exception ill defined. The efflorescence, therefore, as a whole, presented a light erythematous faintly macular form. The individual lesions could be isolated only with difficulty. Over the trunk the skin was everywhere hyperæmic, the lesions existing in such profusion as to constitute an almost solid sheet of rosy erythema. Nowhere could any large split-pea or finger-nail sized macules be found. There was no itching or heat of skin.

The eruption bore more resemblance to common measles than to any other disease, but the lesions were considerably smaller and finer, and were less distinct in outline and lighter in color than in this disease. Owing to the wide-spread diffusion and the punctate character of the eruption, an anomalous case of scarlatina might have suggested itself to an inexperienced observer, but the color was much paler than that met with in this disease. The complete absence of febrile symptoms, moreover, would have precluded it from being confounded with either scarlatina or measles. Apart from the efflorescence there was nothing to suggest measles. The view of the affection being a symptomatic erythema could scarcely be entertained, nor were the lesions large enough or sufficiently defined to suggest the idea of the erythematous syphiloderm. The punctate character of many of the lesions, moreover, was entirely adverse to such a view. The following day the eruption had faded appreciably, and the next day it had disappeared, leaving the skin the seat of the lightest possible desquamation. The whole attack continued about three days. At no period did the patient experience even the slightest malaise. There was consequently no occasion for treatment.

I would add to the history of this case that a younger sister, a child ten years of age, was reported to be just recovering from a slight disorder accompanied with a light erythematous rash, which the family physician had pronounced to be scarlatina. I strongly suspect, from the account given, that it was rather a case of the disease under consideration.

Another case presented itself to my notice at about the same time. I was requested by a prominent physician of this city to see his daughter, about twenty-five years of age, who had an ill-defined general erythematous eruption which had existed four days. The diagnosis, it was stated, was somewhat obscure. Another physician had also seen the patient, but was unable to arrive at a conclusion as to the nature of the disease. The curious feature of the case, it was remarked, was that while the eruption was apparently simple, and there were no symptoms of malaise, the cervical and post-cervical lymphatic glands were all very markedly engorged, and were somewhat painful. I subsequently found, moreover, that the post-auricular glands were also materially enlarged, the whole picture reminding one of the glandular involvement of early syphilis. The history given by the patient was that the first symptom noted was a slight stiffness of the neck, when later the glands were discovered to be affected. This occurred five days previously, and the following day the eruption appeared rather suddenly, as a faintly-marked pale-reddish, punctate, small, ill-defined macular, erythematous, diffuse rash, occupying especially the face, neck, chest and back, arms and thighs. The scalp was also invaded. There was no heat of skin or itching. There had been no malaise, fever, cough, or coryza, the patient remaining in the enjoyment of her usual good health.

I saw the case on the fourth day, when the efflorescence was somewhat paler than it had been and was already beginning to show slight desquamation, so slight, however, as to have escaped the notice of the patient. The lesions were identical in form with those of the first case. Three

days later, all trace of the eruption had disappeared, and the engorged glands of the neck had decreased markedly in size. The patient had been about and upon the street daily throughout the attack, and, apart from the affection of the skin, considered herself perfectly well. The resemblance of the eruption to measles had not, I believe, been entertained by the several physicians who had seen the patient.

A week or ten days later I was asked by Dr. C. H. Thomas to see a little boy, aged six, suffering with a slight general rash. It proved to be the same disease, the lesions of the skin being almost identical with the other cases described. The engorgement of the cervical glands was also a marked feature here. There was, moreover, in this case some malaise, and also slight suffusion of the eyes.

Dr. Thomas informed me that he had been called to see two other children in this household (where there were in all six children) about ten days before, and had found them with very slight febrile symptoms, together with a disposition to sneeze and to cough, which passed off in a few days. About the time that the children were thought to be recovered, however, a general erythematous eruption appeared. It had been undoubtedly a mild form of the disease under consideration. It subsided completely within three days.

I have since learned that ten days after the little boy whom I saw was attacked, the disease made its appearance upon the baby of the family, in the form of a profuse, very fine, punctate, erythematous eruption, without constitutional disturbance; and, moreover, that at the same time a colored servant of the house, a lad of fourteen, was also similarly attacked. In this family, therefore, five children were affected at different dates within a period of six weeks. These cases would seem to prove its contagious nature, were such proof required.

Dr. Thomas further tells me that about a month ago he attended a family in St. Alban's Place, where several children had the same disease in a mild form, and that he had heard that there had been numerous instances of it in the same street, all being of a light type,—in many cases so light that the family physician had not been called upon.

The affection has unquestionably been in our midst certainly for several months, and, latterly, in some localities in the form of an epidemic. Dr. I. Minis Hays, Physician to the Pennsylvania Institution for the Deaf and Dumb, informs me that the disease has existed extensively in this institution during the past two months. The inmates here are from ten to twenty years of age. The disease first made its appearance shortly after Christmas, beginning with the girls, and was confined to them until quite recently, when the boys began to be attacked. There have been about fifty cases of the disease, almost all being among the girls. About one-third of the girls of the institution have been affected. The disease manifested itself in the form of outbreaks, appearing every week or two, when from ten to fifteen would be attacked. These would recover, and in the course of a few days another group of cases would be reported. Its contagious nature was unquestionable. With the exception of five or six cases, Dr. Hays states, none of the patients presented constitutional symptoms, and even in the majority of these there were no marked features of systemic disturbance. When present, it consisted merely of slight suffusion of the eyes and malaise for a day or two. In one case only was there a resemblance to the general symptoms of ordinary measles.

The patients were in good general health. The eruption, indeed, constituted, in the great majority of cases, the only appreciable symptom of the disease. It was pretty uniform in character, varying but little in the many instances observed. The lesions, according to Dr. Hays, as a rule, were more macular, discrete, and defined than in the cases described by me. The average duration of the eruption was from two to three days. In one case only was there noted marked engorgement of the cervical glands, an observation which is altogether at variance with my experience. The efflorescence was without heat or itching. None of the attendants were attacked.

Dr. Hays further informs me of the interesting observation that in the spring of 1880, eight months previously, common measles prevailed in the institution, there having been at this period forty-six cases of this disease, and that about fifteen of this number had recently suffered with the present epidemic of rötheln.

Dr. James Markoe, Physician to Girard College, writes to me, in reply to an inquiry, that the disease also exists at the

present time sporadically among the inmates of this institution. In the children's asylum of the Philadelphia Hospital, on the other hand, no cases have occurred this winter. The chief nurse of this department, a competent observer who has been connected with the institution for many years, tells me that the disease has not been seen here for five or six years, when it occurred as an epidemic. She was familiar with the affection, and differentiated it from measles. It has certainly been some years, according to my recollection, since it was epidemic in Philadelphia. In private practice it would seem that some physicians have encountered it frequently during the past few months, while others, enjoying equal advantages for observation, have not met with it.

My friend Dr. D. Murray Cheston states that he has seen numerous examples of late in different parts of the city, some of them extremely mild in type, others more marked. The eruption, he adds, was, as a rule, of the same character as that described in my first case. About seventy per cent. of the cases have had common measles. Dr. J. Forsyth Meigs also informs me that he has met with numerous instances of late, and that he has always looked upon the disease as a variety of "roseola." The involvement of the cervical glands was a symptom that had not attracted his attention in the cases encountered.

Observations upon the nature of the disease, its relation to true measles, and like questions are all of interest, and it is hoped will receive attention from those whose experience has been sufficient to warrant discussion of the topic.

SPECIAL REPORT IN THE CASE OF S. OBERMEYER, COMPANY D, SIXTH U.S. INFANTRY—PARTIAL SOFTENING OF PONS, CEREBELLUM, AND CEREBRUM.

BY A. IVINS COMFORT,
Acting Assistant-Surgeon, U.S.A.

SYLVESTER OBERMEYER, musician, Company D, Sixth U.S. Infantry, aged 20 years, a native of Pennsylvania, and of German parentage, was under treatment at Fort Buford, Dakota, for headache, from April 15 to April 17, 1880. He was admitted to hospital April 21, where he remained under treatment for remittent fever until June 30. About this time a marked change was observed in his disposition: from being a man neat in his personal appearance and of stylish soldierly bearing, he became listless, inanimate, and neglectful. He now left the hospital at his own request, though unfit for duty, and travelled by boat and rail from Fort Buford, Dakota, to Rawlins, Wyoming. Thence he travelled with a wagon-train to Snake River, a distance of forty-five miles. August 5 he rode in a government wagon to White River, where he arrived August 10. September 26 he left White River with his company, at times riding in an ambulance and at times marching. October 6 he arrived at Fort Garland, Colorado. He was treated in quarters for headache from November 7 to November 12, when he was admitted to hospital, and treated chiefly by bromide of potassium and aperients until November 27, when he was returned to duty apparently somewhat relieved.

When with his company he was inclined to lie upon his bunk or sit motionless by the fire for hours at a time, and when aroused from this condition of listless quietude he became irritable and was inclined to give his comrades short answers. December 21 he was again admitted to hospital, complaining of headache. When asked to locate the seat of pain, he referred it to the back part of his head. The inane facial aspect of the patient was indicative of cerebral disease, so also his attitude and gait. Paralysis of the left motor externus and left facial nerves was so marked as to be detected by non-professional eyes. His tongue, upon protrusion, deviated to the left, and atrophy of its left half was plainly apparent. When standing, he assumed a stooping posture, with his head in a nodding attitude. His impressions were slow, and intellection obtuse. With his body bent forward and his toes inverted, he shuffled along with a rocking, toppling, straddling, staggering gait, apparently anxious at each successive step lest his unmanageable limbs should fail to support him. Paresis of the lower extremities was unmistakably present, existing in a more marked degree upon the right than upon the left side. The power of co-ordinated action, particularly of the lower extremities, was undoubtedly seriously impaired. There was no ptosis upon either side, but paresis of the left lower eyelid existed to such an extent that a perfect closure of the lids was rendered impossible. Its punctum failed to approximate the globe, and the escaped tears were constantly trickling down the cheek, producing excoriation of the part. His appetite was eager, almost gluttonous; his breath offensive, and bowels inclined to be constipated. Fluids were usually introduced into the mouth by the unaffected side, and, by care on the part of the patient, only rarely escaped by the affected angle. Great difficulty was experienced in

the utterance of certain consonant sounds, particularly the labial, and the intonations of the voice were of a slightly husky character. No difficulty in deglutition. That diplopia existed may be inferred from what has already been said; and amaurotic vision was also present. The patient frequently complained of tinnitus aurium. The function of the olfactories seemed to be of normal acuteness. The pulse on admission—apparently not a "pulsus cephalicus"—was slightly accelerated, numbering 82 per minute. Respirations numbered 22; temperature, 98⅕°. The ataxic gait of the patient suggested the existence of tabes dorsalis, or sclerosis of the posterior column of the spinal cord, though it differed from that of tabes in many particulars. The absence of the fulgurating pains and the characteristic cincture of tabes, and the presence of an occipital headache with diplopia and amaurosis, the paralysis of the abducens and portio dura nerves, the atrophy and deviation of the tongue, all precluded tabes from the diagnosis and established the existence of a lesion of the brain. Upon admission, a blister was applied to the occiput and nape of the neck, and the patient was treated with bromide of potassium, mild aperients, an easily digestible diet, and rest.

December 23.—The blister afforded an entire relief of the headache.

December 24.—Pain now was felt over each temple, to which small blisters were applied, and a two-grain solution of the sulphate of zinc was ordered for a conjunctivitis of the left eye.

December 25.—Free from headache. Urine voided about proportionate to the amount of fluids ingested. Specific gravity, 1.023. Reaction acid. The sediment proved to contain, upon microscopical examination and chemical tests, the urates.

January 1, 1881.—Psychical disturbances were now beginning to manifest themselves. The patient was restless during the entire night, disposed to get out of bed, constantly requiring to be watched, night and day, and at times quite delirious. Thirty minims of the fluid extract of ergot, with one-half drachm of the bromide of potassium, were now given every four hours. Diet chiefly beef-tea and milk.

January 4.—Delirium more subdued. Deglutition of solid food difficult. Tracheal râles, slight cough, voice aphonic, respiration hurried, 28 per minute. Pulse, 82. Temperature, 98⅖°.

Patient has been unable to walk or stand for several days, in consequence of lack of co-ordinating power. When lying upon the back, however, he can flex or extend the limbs at will. Vomiting and convulsive movements of the motor system have at no time manifested themselves. No contractures.

January 5.—Delirium entirely subsided. The pulse, though it remains at 82 per minute, is evidently failing in volume, and the extremities are inclined to be cold, for the relief of which dry heat was applied. The two points of an æsthesiometer could not be distinguished from one when separated at the distance of one inch and a quarter and applied to the integument of the cheek, breast, and lower extremity. The prehensile power of the left hand has been much greater from the time of admission than the right. Finely-pulverized sugar is not recognized as such upon either half of the tongue, either by tactile sensibility or by taste. Salt was said to have a "rough" taste upon the left side of the tongue, while upon the right side it was recognized as salt.

January 6.—Patient suffers from retention of urine, and is relieved by the use of the catheter. Pulse, 82. Dyspnœa. Temperature normal. Symptoms of increasing paresis of the inferior laryngeal nerve. Deglutition of solids now impossible. Diet, milk, egg beaten up with sherry, and beef-tea.

January 7.—7 A.M. Pulse, 82. Temperature, 97°. Respiration difficult, at times very rapid, as often as 60 per minute, or even more rapid than the pulse, then apparently suspended for some seconds. Increasing laryngeal difficulty, tracheal râles, a troublesome, hacking cough, without the power to expectorate. Great prostration. The case proved fatal at 9 P.M.

January 8.—Autopsy twelve hours after death. Rigor mortis very firmly established. Body somewhat emaciated. Calvarium scarcely of the medium thickness, readily separated from the dura mater. Longitudinal sinus and other vessels of the dura mater filled with a thin, uncoagulable black blood. General hyperæmia of the meninges of the brain. Arachnoid and pia mater free from opacities or adhesions, copious effusion into the subarachnoid space, fluid clear, free from the presence of pus or blood, or at least apparently so to macroscopic observation. A recent and apparently progressive softening at the inferior aspect of the cortical substance of the middle and posterior lobes of the cerebrum; the continuity of the parts readily crushing under slight pressure of the thumb and finger. The cerebellum was also in a condition of recent progressive gray softening. In the body of the pons Varolii was found a circumscribed locality, of about two-thirds of the size of an English walnut, in a well-marked condition of *white softening*. This locality was circumscribed by the normal tissue of the pons Varolii, and its condition, though not purulent, was of an almost pultaceous consistency. The medulla oblongata also appeared to be undergoing the process of softening. Liver, spleen, kidneys, stomach, and other abdominal viscera normal.

Diagnosis.—White softening of the pons Varolii; recent gray softening of the base

of the middle and inferior lobes of the cerebrum, also of the cerebellum; softening of the medulla oblongata.

Cause of Death.—Paresis of the pneumogastric nerve, œdema of the lungs, and carbonic acid toxæmia.

Death occurred in the systole of the heart's action. The heart normal, and free from endocarditis or pericarditis, its cavity containing a small quantity of very thin, black blood, free from coagulum. Valves normal, and free from fibrinous formations. The pleuræ, both costal and pulmonic, smooth and moist, preserving their polished appearance, and free from adhesions of either recent or remote origin. The lungs were of a dark-purple color, distended to about three-fourths of their fullest capacity, firm and inelastic to the touch, œdematous, and, when cut, free from frothy oozing. Complete splenization existed in their posterior aspect.

Whether the white softening existing in the pons Varolii—which may be regarded as the original lesion—had its origin in a hyperpyrexia occurring with the mountain fever, either an adynamic remittent, or a typhoid, for which the patient was under treatment at Fort Buford during the spring of 1880, or was the offspring of some hemorrhagic infarction due to the altitude of Fort Buford and having its existence prior to the occurrence of the fever, is exceedingly difficult, from either the autopsy or the history of the case, to determine.

The cerebellum, pons, and medulla are preserved as a contribution to the Army Medical Museum.

CASE OF SUDDEN DEATH IN DIPHTHERIA.

BY J. F. WALSH, M.D.,
Camden, N.J.

JULY 1, 1880, called to see C. M., adult; she was suffering from a palmar abscess of diphtheritic origin; considerable general debility. The abscess treated with poultices and opened July 3. July 4, general malaise, chilliness, headache, prostration, sore throat. Examination of throat revealed a diphtheritic patch on uvula; pharynx, half-arches, and soft palate very red and angry-looking; tonsils enlarged, tumid, inflamed. Treatment: milk-punch, beef-tea, etc.; tr. ferri chlor., gtt. x, potass. chlorat., gr. v, every half-hour, alternately; spray—thrown into throat by means of an atomizer—of a mixture of acid. carbol. ♏xx to liq. calcis f℥vj every half-hour. July 10 (two to three days after the first patch of exudation discovered), the whole throat was involved. Up to this date patient had been doing excellently; on this day the following conditions noted: throat devoid of exudation, returning to a healthy condition; tongue very slightly coated; pulse 60, full, but rather weak; respiration normal; slight mental confusion (but this has existed from the beginning of the sickness). Three to four hours after this last visit a messenger came in a great hurry, saying that patient had suddenly got much worse. On my arrival in the room she was dead. No violent symptoms preceded death. Husband says that she suddenly got ashy pale and stopped breathing. No post-mortem allowed.

TRANSLATIONS.

DIFFERENTIAL DIAGNOSIS BETWEEN CHANCRE AND OTHER ULCERS OF THE CERVIX UTERI.—Rasmusow, in an article of great interest both to the gynæcologist and to the general practitioner (*Vierteljahresschr. f. Derm. u. Syphilis*, vol. viii., 1880, p. 517), says that the first point is to decide whether a given sore is a chancroid or a chancre. The points of diagnosis are as follows. The chancroid presents, as a rule, a decided loss of substance, an excavation with undermined and corroded edges, surrounded by a reactive inflammatory area. The surface of the chancre, on the other hand, is usually flat, sometimes elevated, without sharply-defined borders, and rarely shows itself as a decided loss of substance. The floor of the chancroid is uneven, like its edges, corroded, and covered with a more or less abundant yellowish or fatty-looking secretion. The floor of the chancre is smooth, as if varnished, with a grayish or reddish (flesh-colored) appearance, and it exudes a scanty sero-sanguinolent or purulent fluid. The floor of the chancroid is soft and doughy, or only gives the sensation of inflammatory exudation, while the chancre is marked by a well-marked, hard, sclerosed foundation, although this may not be so perceptible in this locality

as in chancres of the external skin. A common accompaniment of the chancre is a painless enlargement of neighboring lymphatic glands, the tumors thus formed showing, in most cases, no tendency to break down into abscesses. A similar involvement is quite unusual in chancroid, occurring, according to Zeissl, only twenty times in one hundred cases. This is particularly the case in chancroids of the cervix, in which it only occurs when these ulcers are accompanied by similar sores on the external genitalia, where abscesses form, as a rule. The chancre is followed by the appearance of general secondary symptoms, while, as is known, the chancroid is a purely local affection. As to inoculation, Rasmusow has not employed this method of diagnosis, first, because in many of his cases the capability of the secretion for auto-inoculation is evident from the appearance of neighboring sores, and, secondly, because at present the fact asserted by Auspitz appears to be proved, namely, that the secretion of the chancre can itself be auto-inoculated until the period of general symptoms.

Of other affections of the cervix which may be confounded with chancre, follicular ulcers, simple abrasions or excoriations, papillary erosions, herpetic ulcers, tubercular and cancerous ulcers, may be mentioned. As to the follicular ulcers, these are small and cup-shaped, situated in the follicles, are most numerous about the external os, and are even found within the cervical canal. They do, indeed, remind one of chancroids at first glance, but they are usually no larger than the follicles from which they originate, and do not tend to spread. Early cauterization generally heals them rapidly, whereas this treatment applied to the chancroid before its surface clears is usually harmful. Follicular ulcers are usually accompanied by enlarged and inflamed follicles, and are grouped about the external os. They are also usually accompanied by catarrh of the cervix, and even of the uterine cavity. The ordinary accompaniments of this catarrh are likewise present, — hyperplasia and hypertrophy of the cervix, fluor albus, burning in the lower pelvic region, pain in the loins, etc. Chancroids of the vagina usually run a painless course, and are unaccompanied by a catarrhal condition of the cervical canal and cervix. Quite contrary to chancre, these follicular ulcers do not run a typical course; they are quite indifferent to the influence of iodoform, which is almost a specific in the venereal sores of this locality. From the initial lesion of syphilis these follicular ulcers can easily be distinguished by their lack of induration and by the absence of swollen glands.

Simple erosions resemble chancroid and chancre only in the earliest stage of the latter; the changes which take place in both varieties of venereal sores, the ulceration of the chancroid, and the induration of the chancre, with involvement of neighboring lymphatic glands, soon serve to differentiate them.

The papillary erosion is simply a further metamorphosis of the simple erosion, and is characterized by small dark-red points scattered over its surface, which are nothing more than the points of papillæ deprived of epithelium which are found in the inflammatory condition. The papillary erosion is usually found in connection with simple erosion, and is accompanied by cervical and vaginal catarrh, the lesions also being grouped around the os uteri.

The so-called herpetic ulcer may sometimes resemble the initial lesion of syphilis, particularly when it takes the form of an erosion; but the herpetic ulcer is apt to be multiple and the several lesions run together, forming a larger sore of very irregular segmented outline. In addition, there is no induration or lymphatic glandular involvement, and the little sores tend to rapid cure.

Carcinoma is usually easy to distinguish from venereal sores of the cervix. The usual crater-like excavation, the depth of the sore, with irregular, thick, hard, bossillated edges; the uneven floor, covered with a dirty-purulent and ill-smelling secretion; the frequently accompanying hypertrophy of the cervix, with immovability of the uterus itself as the growth progresses; the occasional stubborn bleeding; the pain; the microscopic examination showing a mass of epithelial detritus and connective-tissue elements in the discharge; finally, the age of the patient,— all these point to the diagnosis between venereal and carcinomatous ulcers of the cervix.

Tuberculous ulcers of the cervix are almost unknown as primary appearances, and are accompanied by signs of tuberculosis in other organs.

Foreign Bodies in the Uterus.—Dr. Hughes (*Le Concours Médical*, 1881, p. 56; from *Le Praticien*) gives the two following cases. In the first, a physician, in treating a frightful hemorrhage from the uterus, had placed and left in the organ a sponge saturated with toilet-vinegar. When the bleeding had ceased, he did not dare to remove the sponge, for fear of bringing it on again, and the os soon contracted so that it would not admit more than the extremity of the index-finger. The next day preparations were made to dilate the os, when the doctor was agreeably surprised to find the sponge lying in the vagina. In the second case the accoucheur had been obliged to introduce his hand into the uterus to detach the placenta, when a contraction of the organ squeezed it tightly. When the hand was extracted, the doctor found that a ring of considerable size which he had worn at the time was missing: it was supposed to have remained within the uterine cavity. He determined to wait a day or two, at the end of which time, introducing his hand into the patient's vagina, he found the os uteri patulous, and within it the missing ring, which was extracted. Dr. Hughes draws three conclusions from these cases: 1. Foreign bodies introduced into the uterus are not the source of serious accidents. 2. Such bodies should be immediately extracted without hesitation: if not possible to do so, it should be remembered that the uterus can often expel them spontaneously. 3. If interference is necessary, the os uteri is to be dilated for the purpose of extraction. [To these sapient conclusions let us add one more: Do not convert the post-partum womb into a "catch-all." Think how awkward to the young accoucheur to arrive at his front door at 2 A.M., after a hard night's labor, and find that he had inadvertently left his bunch of keys in his patient's uterus.—Ed.]

Bleeding from the External Auditory Passages from Erosion of the Internal Carotid.—Solkowsky (*Cbl. f. Chir.*, 1881, p. 62; from a Russian source) observed the following case. A healthy-looking soldier, 21 years of age, was admitted to the hospital suffering from a discharge from the ear, together with severe headache, chiefly on the left side, and fever. The membrana tympani was destroyed and the sense of hearing entirely lost. Injections of sulphate of zinc were employed, together with the internal use of quinine, under which the fever diminished; the headache, however, continued. On the twenty-second day of the patient's admission, severe arterial hemorrhage occurred by the external meatus, which, however, was checked by the employment of a tampon. Ergot, ice, and rest were ordered, and ligature of the carotid was suggested, which the patient, however, declined. During the following days the hemorrhage recurred daily, both by the meatus externus and by the mouth, in spite of compression of the carotid. Death supervened on the twelfth day after the first appearance of the hemorrhage. Post-mortem examination showed an erosion in the outer and under wall of the carotid three-fourths of a centimetre in length. There was no trace of the membrana tympani or of the ossicula auditus. There was some reason to suspect that this condition of the carotid was due to some injury of its coats by the injection of a concentrated acid. Solkowsky alludes to a similar case of which he had heard.

Pilocarpin in Albuminous Nephritis.—Langlet, of Rheims (*La France Médicale*, 1881, p. 150), has treated a case of the albuminuria of pregnancy successfully by jaborandi. In this case the drug acted as a diuretic, even bringing on hæmaturia. Cantieri has obtained good results in parenchymatous and interstitial nephritis. The infusion of jaborandi may be prescribed in these cases in the dose of one drachm of the leaves infused for fifteen minutes in half a pint of boiling water. As much as a drachm and a half may be used in some cases; but in infants no more than thirty grains should be given. Nitrate of pilocarpin in doses of one-sixth to three-quarters of a grain by hypodermic injection is useful in chronic kidney troubles, in serous effusions, and in œdema of the lower extremities. Muriate of pilocarpin is to be used in still smaller doses. These salts may be dissolved in distilled water or in cherry-laurel water. As pilocarpin reduces arterial tension, the existence of cardiac asthenia is a marked contra-indication to its employment, even although the arterial tension may be reduced and the cardiac contractions insufficient.

Two Unusual Tumors.—A. Bryk (*Cbl. f. Chir.*, 1880, No. 4; from *Archiv f. Klin. Chir.*) reports the case of a seamstress, aged 42, who had a multiple atheromatous

hygroma of the right buttock. The tumor was of twelve years' duration. The bursæ present in the normal condition were changed into large cysts. The larger biloc-ular cyst spread over the posterior part of the buttock and thigh and was as large as the head of a man. Two smaller pear-shaped cysts arose from the glutei. The contents of the cysts consisted of fattily degenerated epithelium, fatty detritus, and crystals of cholesterin; the brawny thickened walls were lined with pavement-epithelium. The diagnosis before operation being difficult, extirpation was practised,—a difficult procedure, and one which necessitated the division of muscular structure. The process of healing was slow, and was followed by anchylotic knee-joint when in a position of extension.

A case of petrifaction of the left mammary gland is likewise reported by Bryk, occurring in a woman of 62 years. The tumor had first been observed eleven months before the operation. It was the size of a goose-egg, hard, nodular, sensitive to the touch, and accompanied by lancinating pains. The patient died six days after the operation, of nephritis. The tumor, which had been supposed to be a scirrhus, turned out to be a hen's-egg-sized calcification of the gland, of which a less-than-bean-sized portion was found remaining. The calcification had taken place in the interglandular connective tissue.

The Absorption and Elimination of Quinine — Experiments of Professor Giulio (*Giornale di Medicina Militare*, October, 1880; from *Gazzetta degli Ospitale*, No. 17, 1880)—Conclusions.

Quinine certainly not eliminated by the saliva, nor by perspiration.

Not absorbed by the skin through friction, even under the most favorable circumstances.

Appears in the urine thirteen to fifteen minutes after a hypodermic injection of it.

Appears in the urine fifteen to seventeen minutes after administration by the mouth, digestion being good. If latter not so, a proportional delay.

Appears in urine twenty to twenty-five minutes after an entero-clysma, if injection retained for any length of time, and thirty to forty minutes after an ordinary enema, if not immediately expelled.

Resection of About Four Feet of Small Intestine—Cure.—Kœberle (*La France Médicale*, 1881, p. 128) has resected the intestine in four cases of cancer of the rectum. In each case there was cure without relapse. The last case, however, is too recent to state the result with certainty. Kœberle has also performed this resection in cases of foreign bodies in the intestine. The case of most interest among those given by Kœberle was that of a girl of 22, who had been suffering for some months with attacks of internal strangulation. Kœberle had recourse to gastrotomy. The loops of small intestine which showed in the wound were distended and congested. There was a cicatrix above and below which the intestine was distended. Resection of a metre and a half—about four feet—of the intestine was attended by complete success, and the patient was cured in about a month.

Convulsions in Carbolic Acid Poisoning.—Treub (*Cbl. f. Chir.*, 1881, No. 4) alludes to the fact that while animals poisoned with carbolic acid always display clonic convulsion as one of the most prominent symptoms, in man this effect is but rarely brought about. He can find only twelve cases recorded. In five of these the carbolic acid acted on the intestinal tract; in four, serous or articular surfaces absorbed the poison; and in three, poisoning took place through the application of the acid to wounded surfaces. (The references are given.) Treub goes on to give a case coming under his personal notice, where a man who had been operated upon for empyema under antiseptic precautions, and whose wound was dressed with carbolic acid dressings, was seized with convulsions, which diminished when this was changed for salicylic acid dressings.

Daily Amount of Epidermis Shed.—E. Salkowsky (*Virchow's Archiv; Cbl. f. Chir.*, 1880, p. 741) says that Moleschott has reckoned the daily loss from the skin of an adult at 14,353 grains (?), of which 2099 (?) is nitrogen, or 4497 grains urea (about one-seventh the entire excretion of urea). Salkowsky is convinced that these figures are probably about fifty times too high. If they were correct, every evening when the clothes were removed clouds of epidermis would fall. Such a considerable desquamation would be inexplicable, even in connection with the absorption of a similar weight of nitrogen. Against this view, also, experiments on dogs militate.

EUCALYPTUS OIL AS AN ANTISEPTIC.—Dr. Bassini, of Parma (*Cbl. f. Chir.*, 1881, p. 68; from *Annal. Univ. di Med. e Chir.*), has followed Schultz in experimenting with the oil of eucalyptus as an antiseptic. He employed for the spray an emulsion, prepared with the aid of carbonate of magnesium, of one and a quarter parts of the oil in one thousand parts of distilled water. The emulsion was tolerably constant. The gauze used was first made, like Schultz's, of fifty per cent.; later, of ten per cent. and five per cent. In addition, Bassini disinfected the locality of the operation with eight-per-cent. solution of chloride of zinc.

As the result of his investigations on animals and man, Bassini concludes (1) that even with ten-per-cent. gauze the smell of the wound is very disagreeable to the patient; (2) considerable infiltration takes place in the neighborhood of the wound, resulting in the formation of pus (this is in opposition to Binz's experience, according to which eucalyptus oil hindered diapedesis); (3) septic decomposition easily occurs (this was not the fault of the *technik*, for Lister's dressing under the same circumstances prevented decomposition); (4) ulceration of the edges of the wound followed the unsatisfactory antisepsis and the inflammatory exudation; (5) eczema occurred so invariably that it could not be attributed to the paraffin and wax in the dressings, but to the oil only.

These facts lead Bassini to the conclusion that, while oil of eucalyptus is analogous to carbolic acid in antiseptic influence, it cannot be regarded as harmless in its effect, and, on the whole, is decidedly inferior to the latter for practical use.

NERVE-STRETCHING IN EPILEPSY.—*Le Progrès Médical* for February 5 contains a further communication upon this interesting method of treatment. In addition to the cases of locomotor ataxia and sciatica treated successfully by this method (see *Medical Times*, January 15 and January 29), three cases have recently been operated on by this method in the Hôpital Bicêtre at Paris. The one reported by *Le Progrès Médical* concerned a woman suffering with congenital epilepsy, in whom elongation of the median and ulnar nerves was practised by Dr. Gilette in the upper third of the arm on December 31, 1880. Although the brief period which has passed since the operation does not permit a definite conclusion to be drawn, it may certainly be asserted that a decided change for the better has been wrought in the patient's condition. The attacks, which numbered ninety a month, have been already reduced to eighteen during the month of January. They are also less severe. The after-effects of the operation itself were next to nothing; the wound united by first intention, and the slight discomfort in the arm experienced by the patient disappeared after the first week.

QUEBRACHO IN DYSPNŒA.—Penzolt's results (published in this journal from the *Berliner Klinische Wochenschrift* about a year ago) have been confirmed recently by Berthold, who has used this remedy in five cases of intense dyspnœa. In one case of very severe convulsive asthma rapid relief was obtained by the administration of the tincture in teaspoonful doses given three or four times within an hour. In a case of emphysema with bronchial catarrh, the same preparation given for twenty-four hours brought the respirations from forty-eight to thirty-two per minute. In a case of pleurisy it failed. The fluid extract has been found useful in diarrhœa.

RESORCINE A DERIVATIVE OF ASSAFŒTIDA.—Dr. Dujardin-Beaumetz has recently experimented with resorcine, a crystallized body, white, odorless, soluble in all proportions. It prevents fermentation in all albuminous substances,—milk, urine, etc. The Germans have used it chiefly for wound-dressings, its action being similar to that of carbolic and salicylic acid. It may be employed in all kinds of ulcerations as a topical remedy, and as a gargle in diphtheria. It is poisonous in large doses. The remedy, in fact, is a substitute for carbolic acid, having all of its properties without the disagreeable odor.

SUBCUTANEOUS INJECTIONS OF NITRATE OF PILOCARPIN IN FETID SWEATING OF THE FEET.—Armaingaud (*La France Méd.*, 1881, p. 128) concludes as follows from his experience in four cases. Hypodermic injections of nitrate of pilocarpin appear to have a curative effect in fetid perspiration of the feet. This effect is without inconvenience to the system generally. Longer observation is required to determine if this curative action is permanent or temporary. Pilocarpin acts by a substitutive derivation on the salivary glands. Pilocarpin cannot be replaced in these cases by jaborandi with the same good effect.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, MARCH 26, 1881.

EDITORIAL.

DR. OTIS.

THE medical profession, as well as the medical corps of the army, has sustained an irreparable loss in the death of Dr. George A. Otis, Surgeon and Brevet Lieutenant-Colonel, United States Army, which occurred at Washington on the 23d of February last. From the memorandum issued by the Surgeon-General we learn that Dr. Otis was born at Boston, November 12, 1830; graduated with the degrees of A.B. and A.M. from Princeton College; entered the medical department of the University of Pennsylvania, and received his degree of M.D. from that institution in 1850; visited Europe, and prosecuted his studies in London and Paris, and, returning to this country, established himself at Springfield, Massachusetts. He was appointed Surgeon, Twenty-Seventh Massachusetts Volunteers, September, 1861, and held this position until appointed Surgeon, United States Volunteers, August 30, 1864. After the close of the war he entered the Medical Corps, United States Army, as Assistant-Surgeon, February 28, 1866, became Captain and Assistant-Surgeon, July 28, 1866, Major and Surgeon, March 17, 1880, having received the four brevets of Lieutenant-Colonel of Volunteers, Captain, Major, and Lieutenant-Colonel, United States Army, for meritorious services during the war. While Surgeon of the Twenty-Seventh Massachusetts Volunteers, he served in Virginia, North Carolina, and South Carolina, and was on special duty in charge of the hospital steamer "Cosmopolitan," in the Department of the South. Assigned to duty in the Surgeon-General's Office, July 22, 1864, he was Curator of the Army Medical Museum, and in charge of the Division of Surgical Records, until his death.

He was well known to all medical men as the author of the splendid series of "Reports on Military Surgery" issued from the Surgeon-General's Office since the war, and as the compiler of the surgical volumes of the "Medical and Surgical History of the War."

With unusual culture, the result not only of study, but also of extensive travel abroad, he brought to the preparation of these reports an amount of information, a persistence in research, and a trained common sense in summing up his data, which, joined to an unusually clear and agreeable style, made his work a model for all writers on military surgery.

To him also are due, to a great extent, the development and arrangement of the surgical sections of the Army Medical Museum, which are the most valuable of their kind in the world. Personally, he was one of the most agreeable of companions and the staunchest of friends. His death, though sudden, was by no means unexpected, for he received his sufficient warning three years ago. He left the third and last surgical volume of his History about half completed; and we venture to predict that no one will feel his loss more keenly than the officer, whoever he may be, to whom will be assigned the duty of carrying on and completing his work.

THE withdrawal of the trustees and faculty of Bellevue Medical College from the advanced position which was taken by them last year has been almost as surprising as was the original assumption of such place. It would have been much better for the cause of medical education, and no less useful to the parties immediately concerned, if the first change had not been made. A reformer who assumes

a position because it is right, and withdraws because it does not pay, does not, by such action, enhance either his reputation or his influence. A man ought to count the cost of war before he enters upon it; and he who runs away at the first reverse deserves the reputation of lack of judgment as well as of cowardice. The hands of minorities in many colleges struggling with majorities will be greatly weakened by the foolish haste of Bellevue; but the ultimate triumph of reform, though it may be delayed, is still assured.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT an adjourned conversational meeting of the Society, held at the Hall of the College of Physicians, Philadelphia, December 15, 1880, Dr. Albert H. Smith, President, in the Chair, Dr. John M. Keating read a paper entitled "Weak Spines in Young Girls, and their Treatment" (page 324).

DISCUSSION.

Dr. Benjamin Lee said that the prospects for the permanence of a nation depended very much upon the health of its girls. No people can hope to continue prosperous while the mothers are subjects of chronic ill health. American women have been looked upon as the type of invalid women. The proper place to look for the correction of these physical evils is the school-room, and especially the manner of sitting. As a rule, every facility seems to be offered to the production of curvature of the back as far as possible, because the desks are placed so that the student must bend over the desk. On the contrary, the book should be elevated so as to be opposite the eye, and the seat should have a comfortable back, strongly convex, fully supporting the spine.

Undoubtedly the emotional type of the nervous system of many young girls may be a factor in producing this relaxed condition of the muscles which forms spinal curvature. The overstimulated brain from ill-regulated studies and exciting food is only able to do an inferior quality and amount of work. The results of food which is indigestible and too stimulating are faulty nutrition and unhealthy development of the emotional and sexual nature. An important point, referred to in the paper as an accompaniment of weak spines, congestion of the ovaries, stands more in the relation of a cause. He had always noticed this slight convexity of the spine in young girls at the time of puberty, and, as a rule, there is coexisting engorgement of the ovaries, as a result of which there is reflex irritation, and more or less effect upon the spinal muscles, not simply debility, but often contraction, usually in the lumbar region. This is the seat also of pain in the great majority of young girls. When the high shoulder is first noticed, the disorder in the lumbar region has preceded it.

As regards treatment by electricity, he could only say that he had been so well pleased with massage and systematic exercise of the affected muscles that he had not been obliged to resort to electricity, and could not therefore give an opinion. The best results can be obtained with massage and proper exercise, if taken in time, before the bones have become seriously altered in their shape or mutual relations.

Dr. Schapringer said that reference had been made to the use of electricity in eye-practice. In his opinion the muscles are not at fault in the cases mentioned, but the dioptric media: the muscles have as much power as in the normal eye. No amount of muscular stimulation would correct errors of refraction and astigmatism.

Dr. W. H. Little observed that in some forms of asthenopia electricity might prove serviceable. In a similar way he had employed it in order to exercise and strengthen the muscles of the tympanum.

Dr. W. R. D. Blackwood spoke in favor of the treatment of muscular debility by faradic electricity. He recommended to faradize only the affected muscles, and to apply the continuous galvanic current along the spine, for its soothing effect. It is better used in the evening, and he had been in the habit of allowing the patient's mother to apply it, after instructing her in regard to mode and duration of the application. This treatment had been found to be very valuable in ovarian congestion, as it favored the establishment of menstruation.

He had also employed electricity in eye and ear disorders, and in selected cases great benefit undoubtedly results from its proper application.

Dr. A. H. Smith said that he had recently had a very interesting opportunity of learning of the effect of systematic exercise upon young girls. He, in company with some friends, had paid a visit to the Girls' Normal School, where he saw thirteen hundred girls collected, who showed remarkable evidence of the value of physical training in their appearance of vigor and robust health. Considering the circumstances and conditions in life of the parents of many of the girls, he was struck by their looks of good health. This was soon afterwards explained by a subsequent visit to the room where the calisthenic exercises are taught. Every girl is obliged to spend an hour in such exercises each morning. Mr. Fetter, the principal of the school, had in-

formed him that prior to the introduction of these exercises it was very common for the students to break down before examination-time, but since their adoption there had been marked improvement in the health of the girls. Anything that can be done to improve the health of the future mothers is of incalculable importance.

Dr. W. R. D. Blackwood said that he was especially interested in the symmetrical development of the body. He found that his little girl was using the right hand exclusively, and he took the trouble to teach her to use the left equally as much. It required only two months to teach her to use the left hand with as much facility as the right. She uses them now perfectly indifferently, and writes as well with one as the other. He also makes her occasionally take her knife and use it in the left hand at the table, alternating with the right. He believes that children can be taught to be ambidextrous, if pains are taken to counteract at home the teaching at the school, where the right hand is given the preference. This practice is very useful for a surgeon, and he had accustomed himself to use his knife in dissecting in the left hand, and now uses the bistoury or saw in whichever hand is more convenient for operating.

Dr. Henry Leffmann confirmed the remarks about the position taken in the school-room, and had noticed it in boys as well as in girls. While the majority assume the usual position, there are some who display much ingenuity in contorting themselves into curious abnormal positions.

Dr. Wm. S. Stewart thought that the weakness of the spinal muscles was largely attributable to the mode of dress: the waist is enclosed in a tight-fitting corset and made as small as possible. He believed that if physicians would warn their patients against this abuse of dress there would be less of ovarian congestion and spinal weakness.

Dr. J. M. Keating, in closing the debate, said that he had been so much interested in this subject of weak spines by observing its effects in young girls, more especially in dispensary practice, that he had considered it of sufficient importance to bring it to the attention of this Society. Since this condition in young girls is commonly associated with so much anæmia and menstrual disorders as often to prevent them from reaching womanhood, it is important to take some steps to cure this evil at its beginning. The example offered at the Normal School of this city in this subject of calisthenic exercises for the students is not followed as much as it should be.

In regard to the mechanism of curvature of the spine, he considered it an important point that the weaker side yielded to the stronger, and the local treatment to restore muscular strength should be directed mainly to the convex.

In regard to his reference to electricity in the paper, he was afraid that he had been misunderstood. Without discussing the question at all, he had wished merely to express the opinion that the battery is a most powerful means of aiding muscular development, when applied properly to the muscle: the reference to the eye and ear had been made in passing only to point out the application of electricity to the small muscles of the body.

The subject under discussion, regarding the causes and treatment of weak spines in young girls, he considered as very important, being closely connected with those forming the basis of most of the chronic affections of after-life, and he insisted particularly upon instituting early treatment.

On motion, a vote of thanks was tendered the lecturer for this interesting paper.

SPECIMEN OF DEGENERATION OF PLACENTA.

Dr. Frank Woodbury presented a portion of a diseased placenta for Dr. R. Bunting, of Roxborough. The patient had had seven still-born children, having been delivered of two living children previously. The general history in the last seven pregnancies was that she felt motion at the usual time, but at the fifth or sixth month it ceased. She would carry the fœtus until the eighth month. The placenta, as in the present specimen, was hypertrophied, heavy, and seemed like a mass of fat. The child was in the present instance macerated, and had evidently been dead for several weeks, although delivered a month before the full time.

On motion, the specimen was referred to the Committee on Microscopy.

INSTRUMENT FOR MEASURING THE VAGINA.

Dr. J. M. Keating presented an instrument for ascertaining the capacity of the upper portion of the vagina in order to determine the proper-sized pessary. The instrument, made by Gemrig, was merely a medium-sized Hodge pessary divided in the middle transversely, and placed upon long scissor-blades, which admit of separation after introduction into the vagina, the degree of separation being marked on a scale on the handles.

Dr. A. H. Smith thought that an instrument that would accomplish what Dr. Keating had in view would be desirable.

Dr. Schapringer suggested that the blades should be separate and introduced consecutively.
